The book is so well written that in spite of the host of alternative devices described, anyone with a taste for nice mechanics will read it through with avidity and then read parts of it again.

PAPER

Paper and its Uses

A Treatise for Printers, Stationers and Others. By Edward A. Dawe. Vol. 1. Fourth edition revised. Pp. xiv+188+28 plates. Vol. 2: Samples of Papers and Boards. Pp. vii+157 samples. (London: The Technical Press, Ltd., 1939.) 2 vols., 15*s*. net.

TWO factors combine to make the task of reviewing these volumes an easy one. In the first place they represent the fourth edition of a work which may now fitly be regarded as a classic of the paper and allied industries; secondly, until recently the author directed the activities of the laboratories of H.M. Stationery Office. Both of these considerations are in evidence in the contents of the book. The treatment of the subject combines, in fact, that authority which is born of many years of experience, and that absence of errors and minor defects which is so seldom attained before a work has passed through its early editions.

As the author states in his preface to this edition, the fundamental processes of paper-making have not altered in the relatively short period covered by the earlier editions of the book. Nevertheless, a combination of scientific skill and improved craftsmanship has resulted in many advances, both as regards the quality of the product and the rate of output. Such developments are the principal new features of this edition, the up-to-date nature of which is indicated by the fact that it includes subjects such as the purification of pulp by centrifugal methods; the manufacture of 'two-wire' and artificially conditioned papers (which have contributed so prominently to the solution of the problems of high-speed printing); the coating of papers on high-speed paper machines; air-mail papers; and standards of permanence and the factors which affect this important property of paper.

The first section of vol. 1 is a brief but clear description of paper manufacture, and it follows the usual lines. It is, however, the two subsequent sections, which deal with the different kinds of paper and paper-products and their uses, which single out this work from the many others on papermaking. Into the space of some sixty small pages is compressed a wealth of detail based on sound practical experience. Nothing of importance seems to have been overlooked, and few of the multitude of varied products which originate as paper are omitted. The final sections deal chiefly with testing methods and standardization (matters with which the author has been specially associated), paper trade customs, and methods for the interconversion of sizes and weights of papers. Here again the author steers his way deftly through the maze of intricacies and traditional nomenclature with which the paper industry is still encumbered, and which his own efforts towards standardization have done so much to help to remove.

In the second volume are bound up 157 samples of typical papers and boards, together with the appropriate descriptive details. This volume is dated 1929, and it seems rather a pity that the opportunity was not taken to bring it up to date also. In some instances (notably the sensitized cheque paper, foil papers and offset papers) the samples included would not find favour among users as typical of the best of their kind. This comment, however, applies only to a relatively small proportion of the samples, and the value of the volume as a whole (especially to the student, for whom it is primarily intended) cannot be over-estimated.

Since the author has now retired from his official position, this work may be regarded as a parting gift to the industry. It certainly deserves to command an appreciative welcome from an industry already so much in his debt for the years of unstinted and able service he has devoted to it. Julius Grant.

ECONOMY OF A PRIMITIVE PEOPLE

Primitive Polynesian Economy
By Raymond Firth. Pp. xii+387+8 plates. (London: George Routledge and Sons, Ltd., 1939.) 15*s*. net.

THE material upon which Prof. Firth has based his study of primitive Polynesian economy in this book was gathered in the course of his expedition in 1929 to Tikopia, one of the islands of the British Solomons group in the Pacific. A valuable study of the social anthropology of the inhabitants of the island already stands to his credit in a substantial volume. He now turns to an investigation from another point of view—a point of view which is claimed, and justly claimed, to be new, namely, that of the system of values which determines preferences in the satisfaction of needs.

The people of Tikopia, it will be remembered by those who are acquainted with Prof. Firth's earlier book, are virtually untouched by White civilization; and in their mode of life they may be regarded as an example of a people of simple backward culture. When, however, this culture is submitted to examination, it is seen that what may be termed their economy, as thus defined, is by no means simple, but on the contrary is of a highly complex character. It is made no easier of understanding in the eyes of a Western observer by the absence of price and its common measure, money. This absence is, of course, a fact which has not passed unobserved by previous observers of life in other primitive or backward communities; and the differences in standards of value and media of exchange have been the subject of instructive study. Prof. Firth, however, is the first to examine the problem to which it gives rise from the point of view of the functional anthropologist, prefacing his study with a consideration of the general question.

Now it must be clear that the study of the economy of a primitive people may be approached from two very different points of view. On one hand the sociologist, and the observer whose record is intended to meet the needs of a Western audience, will make use of a classificatory system and a terminology based upon concepts which in theory, at least, are abstract and of universal application. The anthropologist, on the other hand, in so far as he aims at an accurate and objective ethnographical record, is concerned with a standard of values that is relative—relative to the culture of the people under investigation. It will be remembered that Prof. Malinowski records a striking example in his account of the system of ritual exchange in the Trobriands in his "Argonats of the Western Pacific", while further examples to which reference has been made are afforded by the refusal of the peoples of Africa to commercialize their cattle, or their reluctance to abandon the use of the hoe for more efficient means of cultivation. It is, however, neglect of this principle of the relativity of any given system of values which has vitiated or caused the neglect of the study of primitive economy.

Applying this principle to the people of Tikopia, Prof. Firth shows how in the instance of food, for example, the bare biological need is transcended by values of a non-nutritional order, as a means of meeting social obligations, the responsibilities of kinship, and other ritual requirements; or again in fishing, it is not the remunerative value of the catch which will determine the direction of effort, but ritual which demands that the first catch should be a shark, rather than the less difficult and more profitable flying-fish. Thus the general trend of this investigation may be summarized as showing that the system of values which it might be argued applies to 'economic man' becomes a matter of social relations, and must be considered in the light of that fact, requiring in the study of primitive economics a profound modification in the usual line of approach.

Prof. Firth has produced a most valuable and stimulating study, which will repay careful consideration, not only by the anthropologist, but also by the administrator and others who have to come into intimate touch with any people of backward culture.

CAN CHRISTIANITY SURVIVE?

The Gospel and the Church

A Study of Distortion and its Remedy. By the Rev. Canon Charles E. Raven. Pp. 256. (London: Hodder and Stoughton, Ltd., 1939.) 8*s*. 6*d*. net.

CANON RAVEN examines the character of Christianity in Apostolic days and also in the early centuries, and shows the serious nature of the distortions that occurred. These are more obvious in the formative period between the second century and the collapse of the Western Empire. There were three directions especially in which the primitive Gospel was abandoned: The renunciation of Nature, the distortion of history and the development of institutionalism. Dealing with the first of these he points to the stress laid on miracles, the craze for which had permeated all classes of society, and as a consequence of this obsession religion was identified with the crudest supernaturalism. The pernicious influence of Jerome in dealing with sex is well known and is shown by his deliberate mistranslation of "almāh" as meaning "virgin" instead of "a young woman of marriageable age", and in many other ways as well. He maintained that both Joseph and Mary preserved their virginity and explained the "brethren" of Jesus by asserting that they were His cousins, children of Clopas or Alphæus and another Mary, sister to the mother of Jesus.

In history the distortion is seen in the almost complete neglect of the Gospel records. With the disappearance of the earthly life of Jesus there arose a multitude of saints, some purely mythical, and through neglect of history religion was largely divorced from life. The loss of the sense of the value of Nature and history implied a change in the quality of Christianity, so much so that during the fourth century "it is doubtful whether we ought to say that the Church conquered the world or that the world invaded and subdued the Church".

In order to explain the persistence of the Church's distortion in regard to Nature and history—and we cannot deny that this distortion is still evident—it is necessary to take into account another condition of its early period, the fixing and form of its organized structure. Owing to the rapid crystallizing of Christian institutions and to the form that they adopted, transitory stages of belief became part of the Church tradition. This subject is dealt with by Canon Raven with consummate skill in Chapter v, "The Church Organic and Organized", and he has no hesitation in attributing the lowering of the spiritual standards in the Christian institutions of the third century to the assimilation of Mithraism. The degradation of the Eucharist is described as one of the most tragic of all the distortions of the Apostolic gospel, but many will wonder whether the description given of the superstitions associated with the Eucharist in the third century is not applicable, in part at least, to large sections of Christendom to-day. If Christian orthodoxy refuses to accept the value of Nature and history—a value inherent in its own basic tenets—can it continue to survive in the environment of modern knowledge?

Two chapters, "The Recovery of Nature" and "The Necessity of History" are constructive; but readers will ask how far it is possible to apply in practice all that is advocated. We are told that if we are to learn the lessons that Nature can teach, "it must be by recovering the sense of its wholeness and its value, the humility and the wonder which science in its conflict with religion too largely lost". Furthermore, it appears that the population outside the churches which has discovered the absorbing interest of Nature can be approached by the churches if they free themselves from a distorted tradition. We are disposed to think that Canon Raven has over-estimated the number of people with the "absorbing interest in Nature". In addition, the form of Christianity that would result from his suggestions would be too emaciated for the great majority of people (we are, of course, considering the adherents of Christian tenets outside Anglicans and Protestant Nonconformists), and many would find refuge in magic, charm, talismans, etc., rather than in a religion largely devoid of the element of mystery. It is certain that Mediterranean Christianity would never assimilate a religion similar to that of the Apostolic days. Again, if we recover a sense of the importance of history, is it possible to believe, remembering the reaction against liberalism from which so much was expected, that a synthetic theology will ensue out of the antithesis of recent years and restore to us the proportion of the faith? Throughout his constructive scheme Canon Raven, in the opinion of the present reviewer, appears to have largely overlooked the strong appeal still made by the pagan elements surviving in Christianity.

The book can be recommended because it contains so much with which all reasonable Christians can agree.

M. Davidson.

WAR AND RECONSTRUCTION*

BY DR. JULIAN S. HUXLEY, F.R.S.

EVERYONE realizes, though with very different degrees of awareness and to the accompaniment of feelings that range from ardent hope to sullen resistance, that this War is bound to be followed by radical changes in the structure of separate societies and the organization of the world. In this connexion, biological analogy is helpful not only in creating a general background against which to envisage the coming change, but sometimes in suggesting detailed points in the new order.

In the first place, biology reminds us that change is the normal (though not the universal) rule of life, that certain aspects of biological change can legitimately be called progress, and that man is biologically speaking a very recent type, whose social organization is still primitive in the extreme when looked at in the light of evolution. The lesson of biology for the resistant conservative is therefore that his resistance to change in general is not only useless but also immoral.

But biology has also a warning for the over-enthusiastic progressive. Biological change has normally (though probably not universally) been a very gradual process. The rate varies considerably as between different lines of descent, and at different periods of the world's history, but the change is normally effected through step-by-step alterations of existing organization. In general, it is as frequent for old organs to be converted to new uses as for wholly new organs to be evolved. The zeal of the revolutionary for getting rid of the old system root and branch is thus likely to be wastefully destructive and in the long run to delay progress.

From the point of view of human biology, what are the chief features of the present time which have altered man's social environment so much that corresponding alterations of social organization are needed to meet them—and which, incidentally, have helped to bring about the War ?

The first is the increase in the efficiency and speed of transport and communications, accompanied by the virtual abolishing of frontier space for expansion. This is forcing the remotest regions of the world into often unwilling interaction. It on the one hand provides a potential basis on which world unity could be built, and on the other makes the lack of that unity more and more disadvantageous.

The second is the increase in the potential of power available to States. This is most dramatically seen in respect of war. Armaments have become many times more efficient during the last twenty years. The result is that war has grown out of scale with its function. During many centuries it operated, wastefully enough, yet with a certain efficiency, in adjusting the variations in the balance of power caused by geographical discovery, economic change, and population pressure. But to-day, both its destructiveness and its expensiveness have got out of hand, and have become wholly incommensurate with any positive results which its agency may help to accrue. This, however, is not the only way in which State power has shot up. The dictator regimes have taken into their own hands the organization of economic power and also of the power of opinion. They are in literal truth totalitarian.

The biological analogy shows that for competing nation-States merely to respond to this challenge by corresponding permanent changes in their own organization (however necessary such changes may be as a temporary measure) would be to court disaster. Size and armament alone lead up a cul-de-sac. The giant reptiles of the Mesozoic included the largest carnivores the world has ever seen, like the Tyrannosaurs, and the most heavily armoured animals, like the Stegosaurs and the Ceratopsians. They answered bulk with bulk, aggressive with defensive warfare. But they were all doomed to extinction as soon as the changing environment gave the insignificant but brainier little mammals their chance. The contraction of the world due to better communications provides the corresponding change of environment to-day ; brain-power spent on devising new systems is inevitably destined to supplant the present armoured monsters of the nation-State era. The only question is whether it shall be now, or after more waste and destruction.

A third fact of the utmost importance in the modern world is the search for a new mystic, a new super-personal driving force. Traditional religion of the supernatural type has lost both ground and grip : the curious materialist-idealist compound which expressed itself in the nineteenth century's belief in the inevitability of progress, in the power of knowledge to mould human nature and produce almost millennial prosperity and peace, has wilted in disillusion. In their place, three great nations have already erected new pseudo-religions, all of them involving the glorification of the State. The most radical is that of Nazi Germany, which uses the race-concept as its mystical basis, while for Italy the mystic is the nation, and for Russia the millennial picture of the truly Communist society, when Government will wither away.

---

* Substance of the British and American Association Lecture delivered before the American Association for the Advancement of Science at Columbus, Ohio, on December 30.

In all these cases, however, the mystical driving concept is linked with the national organization of power: and this inevitability has brought a recrudescence of intolerance, persecution, and cruelty which has contributed largely to the final shattering of the belief in progress in other nations. History teaches us, however, that intolerant persecution always arises when an unintelligent mystic doctrine is held with such intensity that the end is deemed to justify the means; and that the persecution will be violent and brutal when the mystic doctrine is bound up with the system of power.

Two by-products of this situation are to be noted. First, the unprecedented refugee problem which it has created—unprecedented partly because of the violence and extent of the persecution, partly because of the nationalist unwillingness of other States to absorb new alien elements; secondly, the distortion of truth which it has brought about, with resultant lowering of the quality of scientific research in the countries concerned. A biological analogy here would seem to be the incredibly small size of the brains of the giant Mesozoic reptiles.

The fourth great feature of the present is the trend away from *laissez-faire* and individualism towards planned organization and collective action. During the period of rapid industrial expansion in the nineteenth century, *laissez-faire* individualism worked well enough, in spite of all its attendant horrors of slums, exploited labour and imperialist expansion. Indeed, it is probable that no other system could have so rapidly mastered the forces and resources of the world. But to-day, like war, it is defeating its own ends and proving unsuitable for its functions. It is proving unsuitable for four reasons; first, because unplanned individualisms, as the world contracts, tend to cancel each other out; secondly, because its basic time-span is too short for many types of projects—the individual demands a return on his money within his own lifetime, or at least for his children. Thirdly, because the agent is too localized; the individual demands a return to himself or to his family, whereas many projects are desirable by making a return to the community in general, through better health, greater taxable capacity, higher standard of living and increased consumption demands, and so on. Fourthly, because it prompts the recurrent vicious cycle of trade boom and trade depression.

Already the world has moved far from simple *laissez-faire*; but the present system is a compromise, and the agencies of collectivized planning are as yet extremely imperfect.

The fifth point is the gradual evening out of world resources in raw material and power. This has been accomplished partly by new methods (for example, utilizable nitrogen from the air instead of from Chilean nitrate beds); partly by artificial substitutes (synthetic dyestuffs; artificial silk; plastics); partly by new transformations of old sources of material or power (motor spirit from coal; hydro-electric power); partly by substituting new raw materials for old (aluminium for heavy metals). The net result has been that, while many inequalities of distribution remain (U.S. helium; Canadian nickel, etc.), the bulk of natural resources is becoming much more uniformly spread over the habitable globe.

The sixth striking feature of our time is the great increase in leisure—some of it in the compulsory form of unemployment and retirement at comparatively low ages. (During actual war, much of this leisure is of course abolished.) The totalitarian countries have made some interesting attempts to provide social organizations for the better utilization and enjoyment of leisure, but so far in other countries the individualistic *laissez-faire* tradition, which tends to regard State-controlled organization as undesirable interference, has prevented any real evolution in this direction.

Seventhly, there is a new approach to colonial problems. Partly this is due to the jealousy of the 'have-nots', a normal phenomenon whipped up to exceptional intensity under the pressure of nationalistic feeling; but in large measure it is due to a new attitude, which has already found expression in the mandatory principle, and to a dawning realization of world unity and the part to be played therein by peoples whose social development has been retarded.

We have drawn one evolutionary analogy—that of the over-armed and under-brained reptiles of the late secondary era. We cannot, however, suppose that the subsequent course of biological evolution will serve as a pattern for the next phase in our own history. This would imply that the over-armed nation-States would disappear and their places be taken by smaller nations more concerned with flexibility and intelligence of social behaviour. This is ruled out by the shrinkage of the world. Do not let us forget that man differs from all other major biological types in consisting of but a single inter-fertile species, in possessing much greater control over the environment, and with the power of forming much larger communities. The only possible climax for such a type is that it should extend over the entire habitable globe in the form of a single community, whatever the organization of that world community may be. All intermediate stages, of racial, tribal, national groups, are, in the long perspective of evolution, inevitably unstable.

But for the immediate future, both biological analogy and historical experience demand a step-by-step advance. Some functions are sufficiently advanced to be put on a world footing without dislocation, while for others the step can only be on to a regional basis. The chief functions which could be stepped up to a world platform are those concerned with primary products and raw materials, with certain aspects of research and of communications, and with sea-power. The chief functions for which we must be content with the intermediate regional set-up are the political, in the broad sense of the word.

Let me amplify this second point first. National culture and tradition, usually combined with language, is the strongest political force in the world to-day. So-called race problems, when analysed, always turn out on analysis to owe their acuteness to differences in culture and economic level which happen to be associated with genetic differences. It is wholly premature to envisage any immediate world-government which could stand up to the tensions introduced by existing differences in national culture. Regionally, however, there is a hope.

The U.S.S.R. has already established a federal system over one-sixth of the world's land area. Pan-America is beginning to emerge. The present struggle between Japan and China could without too great difficulty be forgotten in a Far Eastern federation. Malaya and tropical Africa are destined by Nature to take their place as world regions as their inhabitants progress toward economic efficiency and political self-government. Finally there remains Europe, in the cultural sense of the area where Western civilization arose and where it still flourishes, however impeded by the barriers of nationalism and the counter-currents of totalitarian philosophy—regionally the geographic Europe minus European Russia but plus the Asiatic and African fringes of the Mediterranean Sea.

The most urgent political post-War task is the settlement of Europe. It is here that the greatest number of powerful nationalisms occur, here that they are most crowded, here that the ownership of tropical territories is chiefly concentrated. Geography and history dictate a regional solution for this area, now torn by war. And the War is a civil war, between different representatives of the European tradition—the tradition based on Greece, on the Roman Empire, on Christianity, on representative government, on the spirit of modern science and industry.

Yet the differences between the various nations or groups of nations within Europe are so great, their separate traditions within the enfeebled European tradition so strong, that it would be hopeless to attempt at one bound a full-fledged federal system like that of the United States. On the other hand, a League system, even if confined to Europe, will not be enough; the experiences of the League of the American States prior to their federation reinforces the lesson of the last twenty years. A League system will not work because it is a contradiction in terms: the absolute sovereignty of its member States is irreconcilable with collective action for the benefit of the whole. Some abrogation of sovereignty—in other words some step towards federation—is essential.

What is the minimum degree of federation which would be effective? An executive organ, an advisory organ, an organ of discussion, a training organ, an organ of opinion, a budget, and, in the present state of the world, alas, an armed force. The executive organ would be restricted to a council, in which smaller countries could be represented groupwise. The organ of discussion would be some sort of assembly, not necessarily elected by Western democratic methods, but representing functions as well as regions. For training there is needed some form of international staff college; for moulding opinion back toward unity and away from nationalist separation, a broadcasting service and perhaps a film unit and newspapers and periodicals. The budget might be raised as a percentage levy or in various other ways: the one essential is that it should be adequate in amount —at least a hundred million pounds per annum. Inadequacy of finances was one of the reasons for the failure of the League. The extent of the inadequacy may be seen from the fact that the total of the contributions of member States during any of the last few years was just about as much as what the London County Council spent annually on main drainage alone! As for armaments, if the European council alone disposed of military planes, heavy tanks and heavy artillery (the manufacture of which cannot be kept secret), effective disarmament, both qualitative and quantitative, could be imposed on member nations, and yet Europe as a whole would dispose of a powerful force. The units of the force should presumably be stationed whenever possible in the territory of small nations; that would be an important contribution on their part to collective security.

The budget would be mainly employed, apart from armaments, on long-term development schemes which would not readily attract private capital—partly in Europe (and there mainly in the less-developed nations, though special projects could be contemplated in any country), partly in the colonial dependencies. But a reasonable fraction would be reserved for the other European agencies and for leisure organizations on a European scale.

To these last I shall return. Meanwhile let us consider world organization. The most important of these would deal with primary products and raw materials, and their basic function would be first to iron out the vicious cycle of slumps and booms, and secondly to promote a higher standard of living through higher consumption. The League has been blamed, perhaps rightly, for its lack of proper organization on the economic side. It is, however, fair to remember that in 1919 the machinery for large-scale control of raw materials was virtually non-existent. Most of it was called into being by the great depression of 1929 and subsequent years. It exists in the form of cartels and other international schemes for commodity control. From the technical aspect of economic machinery, these have been much improved during the last decade : it remains to alter their direction, to harness them in the interests of consumption and of the general public instead of permitting the dominance of a policy of restriction and short-term profits for sectional interests. From the technical point of view, the provision of really adequate buffer pools and the wholehearted application of scientific research would also lead to improvement.

They would be under a Permanent Commodities Commission of the League of Nations or whatever world international organization took its place. In addition, such a body would have the duty of canalizing world long-term investments for development purposes, partly in the form of rural loans and the like, partly indirectly through the setting up of development commissions and of what might be called international chartered companies, to promote the general development of backward areas. Development commissions, somewhat on the pattern of the Tennessee Valley Authority, would be suitable for self-governing areas where co-operation can be effected with local government authorities ; while the chartered company type of organization will be needed for dependent (non-self-governing) territories. Such bodies would (as with similar semi-public organizations like the London Passenger Transport Board) be compelled to return all profits above a fixed rate into the area for which they were responsible.

We may take colonies next. Here, as with Europe, the task is to steer a safe course between the Scylla of doing nothing and the Charybdis of attempting too much and seeing the shaky edifice collapse. It is easy enough to say, as many people are saying, that all colonies should be handed over in the immediate future to an international commission. But would it work ? Those who know something about native peoples and the problems of tropical administration say no. There must be somewhere in the system a firm organ of authority and an adequate focus for the loyalty both of those administered and those who administer them. Until the incipient federation of Europe that we have outlined grows into a true federal government, and until training and tradition have produced an *esprit de corps* in the international administrative service, these essential organs of colonial administration will not exist internationally. To take a somewhat remote and yet valid biological analogy, before the adequate development of the cerebral cortex, lower vertebrates had to delegate most of their behaviour to a rather poorly co-ordinated system of reflexes and simple instincts.

The remedy would seem to be retention of the principle of national and executive authority at the periphery, with a reasonable and increasing degree of international non-executive control at the centre. The separate colonies and their administration would remain British, French, Belgian, and so on, though they should all be put on the footing of mandates, and the Mandates Commission strengthened by the grant of powers of investigation on the spot in addition to mere review of policy. Under the European council would be established a colonial commission, truly international, with small but picked international staff of research workers, experts and travelling advisers, and the power of allocating considerable grants out of the European common budget for education, for health, for conservation, for roads and other public works.

It would be desirable that a small but progressively increasing fraction of the technical and perhaps later of the administrative posts in the local service should be thrown open to nationals of other countries ; but the appointments should be in local hands, not in those of the international authority.

A somewhat similar system works quite successfully between the Federal and State authorities in the Tennessee Valley Authority, and it ought to work well enough in the colonial sphere. The scheme would have to be modified in the minor colonial areas, such as the Caribbean and the Pacific, to allow of the participation of other powers, for example, the United States and some of the British dominions.

Do not let us forget that international administration is *per se* no solution of the basic colonial problem, which is the development of the colonial territories and their inhabitants towards self-government. It could only help at the European end, in reducing jealousy among the great powers. But even the partially international scheme set forth above would remove most of the political objections to the transferring of colonial mandates to other powers.

Meanwhile the world organization, too, through its international chartered companies, its world loans, and its expenditure on research, would be aiding in the progress of the tropical countries. The international staff college would have its colonial section, and after perhaps a generation, there would have been built up a truly international *esprit de corps* among the staff.

I mentioned the growth of leisure and the need for its better organization. This is especially urgent in Europe, for it will be largely through such organization that the people of its separate countries will be able to understand the European tradition and to participate in it, only so to experience the greater European loyalty which will render the lesser national loyalties innocuous, a source of local but co-operative pride instead of a source of jealousy and hate.

To do this, the democracies must learn from the totalitarian States ; they must build up their own leisure organizations, and then extend the principle internationally. One can think of so many ways in which such organizations could promote "life, liberty and the pursuit of happiness" on the international plane. Properly organized travel in international parties ; youth hostels, walkers' and climbers' hostels, all over Europe. International festivals like Salzburg in the old days, or Oberammergau, but more numerous and made available to many more people ; an international system of holiday camps, of summer schools, of study and hobby groups, of retreats, dotting Europe from end to end. The whole could easily be linked up with the extension of the exchange system which will be necessary on the educational side—exchange of undergraduates, of graduates, of teachers and professors, to a certain degree of schoolboys ; and also with international schemes of refresher courses for administrators and professional men of every description, and of adult education. One may even envisage the substitution of citizen service for military conscription, and the placing of that, too, on a broad inter-European basis. In all such ways, Europe could become a reality to its inhabitants, and the onward flow of its great cultural tradition would be reinforced.

Let us try to envisage what improvements such changes would bring about. Nationalism and self-determination would not disappear ; but they could be relegated to the cultural sphere, as has been done within the U.S.S.R., and banished from that of economics and power politics. Political boundaries and national Governments would continue to exist ; but their importance, and especially their importance in causing trouble, would be reduced. The risk of conflict between major regions would remain until the time was ripe for world as opposed to regional federation. But the financing of development schemes in the poorer or less advanced countries, and the reduction of economic distress by ironing the bottom out of depressions and by planned schemes for world production and distribution of raw materials and primary products, would remove some of the chief causes of unrest and war.

Friction and difficulty will remain : we have the fundamental biological analogy of hostile symbiosis of the parts within the body to remind us of that. But man and his societies are organisms, albeit with their own unique nature ; and the equally fundamental biological analogy between animal and social evolution shows us that the difficulties can be overcome, and the friction of the parts subordinated to and even utilized for the benefit of the whole.

But do not let us delude ourselves into thinking that it will be easy. Wishful thinking issuing in impractical schemes is one of man's unique biological attributes. Historical experience demonstrates that the most important line of evolutionary progress has been through the improvement of brain mechanism, notably the mechanism for acquiring knowledge and correlating it with action.

The corresponding social machinery is yet in its infancy. The end of the War will face the world with a task for which it is ill prepared. But again, do not let us attempt any ideal or complete plan, any grandiose scheme for which the world is not ripe. That was one of the causes of the League's failure : it was an attempt to impose a ready-made plan, and public opinion was insufficiently prepared for any idea of world citizenship. Rousseau and the Encyclopædists had been preparing opinion for a radical change in society for half a century ; without that, the French Revolution would have been a fiasco. The idea of supernational organization had not penetrated beyond a limited circle of intellectuals, and even they had not had time to work out their ideas in detail, before Wilson sought to impose it in reality. To-day we have at least had twenty years of discussion, together with some bitter if salutary experiences. If the leaders of thought in the various nations can now work out a less pretentious but more workable plan, and at the same time can prepare public opinion for the idea of a dual citizenship, national and world, this War may be the occasion for taking a small but decisive step away from war and towards a world organization of humanity.

CANCER-PRODUCING CHEMICAL COMPOUNDS

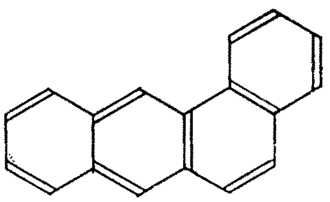
BY PROF. J. W. COOK, F.R.S.,
UNIVERSITY OF GLASGOW

IN the last resort, the degree of importance which is attached to the carcinogenic substances depends upon whether such compounds are concerned in the etiology of 'spontaneous' human cancer. Perhaps closely bound up with this question is another unsolved problem of outstanding importance, namely, the manner in which these compounds bring about a transformation of normal cells into malignant cells. At least until answers are forthcoming to these questions, the carcinogenic compounds will continue to furnish useful material for the experimental study of cancer. Industrial cancer, in its various forms, has stimulated the researches which have brought to light the cancer-producing properties of the various carcinogenic agents, and in the preparation of the present brief survey of these agents regard has been paid to the correlation of the various forms of industrial cancer with their causative compounds.

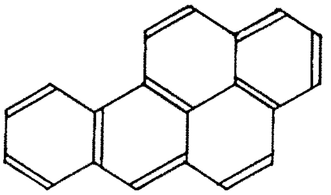
In the earlier work on the carcinogenic properties of substances the skin of the mouse was usually employed as the test object. This was due to a number of reasons. Results could be expected comparatively rapidly; the ear of the rabbit, which had been first used, was less satisfactory in this respect. Moreover, the modes of application of the substances under examination were considerably restricted by the toxic and inflammatory properties of the crude mixtures which it was necessary to use. Many of these difficulties have been resolved by the availability of pure chemical compounds of high carcinogenic potency, and in recent years new techniques of administration have been developed, so that malignant tumours have been induced in a large number of different tissues, and in several different species. One outcome of these and other studies has been the revelation that, in certain strains of animal, tumours of a particular organ are apt to occur spontaneously. Thus, some strains of mice show a high incidence of mammary carcinoma; other strains show a high incidence of lung cancer; and there is at least one strain of mice in which liver-cell cancer (hepatoma) is apt to arise spontaneously. These findings indicate the caution that must be used in interpreting the results when cancers of such organs are found in experimental animals, especially when the tumours arise at sites other than that of application of the carcinogenic agent. Yet even so, tumours clearly attributable to the treatment have been found, usually at the site of application, in a variety of tissues of animals treated with carcinogenic compounds. In this respect the most versatile substances so far found are contained in the group of polycyclic hydrocarbons, mostly related to 1 : 2-benzanthracene (I), in which substituents are present at certain well-defined positions in the molecule. With these compounds malignant tumours have been obtained, usually in mice and rats, in such tissues as the skin, the subcutaneous tissues, the peritoneal cavity, the liver, the prostate, the forestomach, the brain, and the spleen; and this list is not exhaustive. Less widespread in their effect are members of other classes of compounds, where usually carcinogenic action has not been shown except in a single organ. In this connexion it needs to be borne in mind that these substances have not usually been so widely investigated as the polycyclic hydrocarbon class.

The earliest form of industrial cancer, recognized as such in the latter part of the eighteenth century, was the cancer of the scrotum to which chimney sweeps were specially liable. This was caused by soot, and the pursuit of the clue so provided culminated eventually in the isolation from coal tar of the individual compound responsible. This is 3 : 4-benzpyrene (II), an aromatic hydrocarbon, the relationship of which to 1 : 2-benzanthracene (I) is apparent from the formulæ. 3 : 4-Benzpyrene is undoubtedly the principal cancer-producing constituent of coal tar. It has a high boiling point, and hence is present to an appreciable extent only in the highest boiling fractions of the tar. There are grounds for inferring that this or a similar compound is responsible for the carcinogenic properties shown to varying degrees by some of the mineral lubricating oils. Prolonged contact with industrial products of these types is now recognized as being fraught with danger, and the use of suitable precautions should lead to diminution if not to eradication of the form of industrial cancer which they are liable to cause.

The widespread use of tar in road surfaces, and the publication of statistics which appear to show that cancer of the lung is increasing at an alarming rate, have led to the suggestion that tarred road dust may be partly responsible for this increase. This suggestion has been tested experimentally;



(I)



(II)

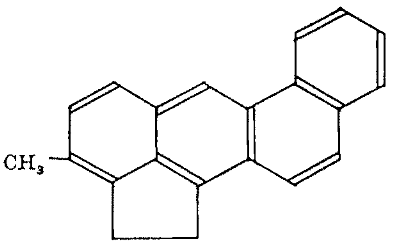
but although an increase in lung cancer was found in mice breathing air impregnated with road dust, this increase was not wholly related to the presence of tar in the dust, and the results of the experiments do not directly implicate such an agent in the increase of the human disease. Furthermore, it is considered by many authorities that the recorded increase in lung cancer is largely accounted for by improved methods of diagnosis. Unconvincing attempts have also been made to implicate pollution of town air by soot, exhaust fumes, etc., and also tobacco smoking in the increase of lung cancer. However, the knowledge that the agencies in question may be, and sometimes are, associated with carcinogenic substances, does not allow such speculations to be too lightly dismissed.

The carcinogenic activity of 3 : 4-benzpyrene is of a high order, inasmuch as tumours arise in a large proportion of the treated animals, in a relatively short time. A somewhat greater potency is shown by 20-methylcholanthrene (III), a hydrocarbon first obtained by chemical transformation of the bile acids, and later indirectly from cholesterol. Other hydrocarbons of similar structure have similar high activity. An altogether higher order of activity, judged by the criterion of shortness of the latent period in the induction of skin tumours in mice, has recently been found in a small group of hydrocarbons typified by 9 : 10-dimethyl-1 : 2-benzanthracene (IV). These compounds, which are characterized by the presence of methyl groups in the positions shown, have in mice skin given tumours which frequently made their appearance within a month of the first application.

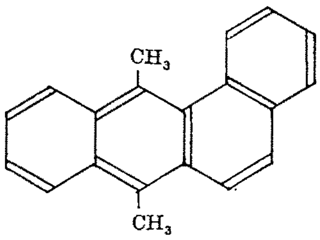
It will be observed that the carcinogenic hydrocarbons thus far mentioned are all derived from 1 : 2-benzanthracene (I). A very considerable number of other carcinogenic derivatives of 1 : 2-benzanthracene is now known. These are purely synthetic compounds, not known to be associated with either industrial or naturally occurring products. Their chief interest lies in the large number of closely related compounds which have been shown to have such biological activity, and in the generalizations which it has been possible to arrive at regarding the correlation of carcinogenic activity with molecular structure and with other properties.

The benzanthracene group is not the only group of polycyclic hydrocarbons with carcinogenic properties. Feeble activity is shown by 3 : 4-benzphenanthrene (V), and systematic examination of homologues and derivatives now in progress is pointing to the conclusion that much enhanced activity is shown when suitable substituents are introduced into positions 1 and 2, but not into other positions of the molecule. Before 3 : 4-benzpyrene had been isolated from coal tar, it had been claimed erroneously that chrysene, also a coal tar constituent, had carcinogenic properties. This error appeared to be due to the incomplete purification of chrysene of coal tar origin. These and other circumstances have caused some attention to be devoted to chrysene derivatives, and a number of chrysene homologues, selected in a haphazard way, have been synthesized and found inactive when tested biologically. More recently a consideration of the structural relationship among the carcinogenic derivatives of 1 : 2-benzanthracene and 3 : 4-benzphenanthrene led C. L. Hewett (*J. Chem. Soc.*, in the press) to synthesize 1 : 2-dimethylchrysene (VI), and this hydrocarbon has been found to have definite carcinogenic activity when tested by application to the skin of mice.

For many years it has been recognized that the operatives engaged in certain sections of the

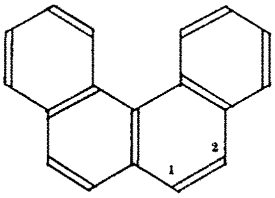


(III)

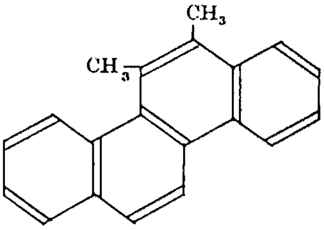


(IV)

chemical industry, and especially in the manufacture of dyestuffs, are more liable to cancer of the urinary bladder than is the general population. This form of cancer was long known as 'aniline cancer', and the prevailing opinion for many years has been that it is due to absorption of nitrogenous bases such as benzidine and the naphthylamines, especially β-naphthylamine. Until recently the evidence was purely circumstantial, and many unsuccessful attempts have been made to induce experimental tumours with these bases. Some two years ago, however, the production of bladder tumours in dogs given, subcutaneously and orally, large daily doses of a high grade of commercial β-naphthylamine was reported by American workers. It was doubtless the prevalence of this dye-workers' cancer, coupled with the known cell-proliferating properties of Biebrich Scarlet *R*, which led to Japanese researches which have shown that a number of relatively simple azo compounds have carcinogenic properties. The principal active compounds which have been revealed by this work are 4'-amino-2 : 3'-azotoluene (vii), which gives liver-cell tumours when fed to rats and mice, 2 : 3'-azotoluene (viii), which gave malignant tumours of the urinary bladder in rats, and *p*-dimethylaminoazobenzene (ix), which is mainly carcinogenic towards the liver.

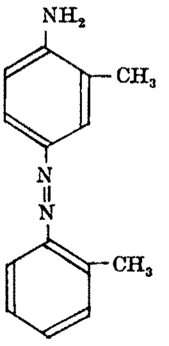


(v)

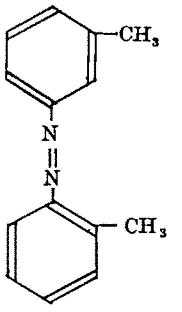


(vi)

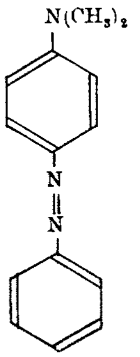
In view of the possibility that contaminants of the naphthylamines might be responsible for the dye-workers' cancer, a number of possible transformation products have been administered to rats and mice in the research laboratories of the Royal Cancer Hospital, London. Mice treated with 2 : 2'-azonaphthalene (x) by application to the skin, or by subcutaneous injection, or by feeding, have developed many liver growths, some of them liver-cell carcinomas, but most were of a cholangiomatous type. Similar tumours were obtained with 2 : 2'-diamino-1 : 1'-dinaphthyl (xi), a product which arises easily by intramolecular change of the dihydride of (x), and also with 3 : 4 : 5 : 6-dibenzcarbazole (xii), which is formed by deamination of (xi). There is thus the possibility that the biological effects of this series of compounds are due to a common metabolite, and it is worth noting that the final product of the series (xii) has a structural resemblance to the carcinogenic polycyclic hydrocarbons.



(vii)

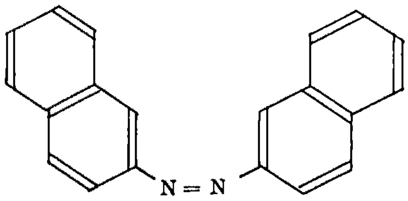


(viii)

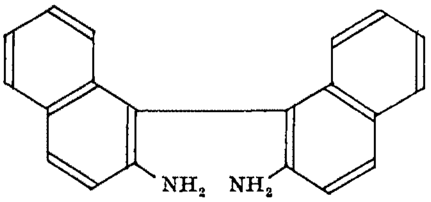


(ix)

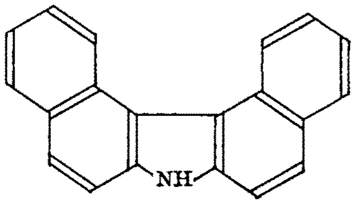
One of the azo dyes found to be carcinogenic to the liver by the Japanese workers, namely, *p*-dimethylaminoazobenzene (ix), was formerly used as a food colouring matter under the name of 'butter yellow' and has also been used in dyeing leather. Fortunately, its use in these respects appears now to be obsolete. In Great Britain the range of permitted food colouring matter is now very limited. With the co-operation of the Government Chemist, tests have been carried out in which



(x)



(xi)



(xii)

relatively large amounts of a selection of these permitted dyes were regularly administered with the food to rats and mice. The compounds chosen were azo compounds bearing some structural resemblance to the azo compounds discussed in the present article. They are mostly water-soluble sulphonates, a circumstance which facilitates rapid elimination. In a few of the mice stomach tumours were obtained; but it is by no means certain that these were due to the dyes.

Existing knowledge of the structures of the various carcinogenic compounds and of the conditions under which they may be formed has led to various speculations regarding the possibility of such substances being present in human food. Some workers have recorded the production of skin tumours by heated fats and by tars prepared by heating coffee. It has been claimed also that wheat-germ oil prepared by a special extraction process produces sarcomatous tumours in rats. This claim has not thus far received independent confirmation, and at the present time there is no evidence that cancer of the internal organs is due to specific dietary constituents. However, it is evident that such lines of inquiry should be pursued.

A puzzling and in some ways disconcerting feature of the carcinogenic agents now known is their variety and their apparent lack of correlation. It may be recalled that cancer may be induced not only by the classes of compound reviewed in this article, but also by several other agencies. The malignant tumours which arise in consequence of exposure to ultra-violet light, X-rays, and radioactive substances may well be due to the production of carcinogenic compounds from normal constituents of the tissues.

There is, however, no evidence that the radiations exert their influence in this indirect manner. Cancer of the skin occurs in persons taking arsenic by mouth over long periods, and has also been found in workmen engaged in handling arsenical sheep dips. Teratoma of the testis in fowls can be induced by injection of zinc salts at the season of the year when the testis is actively secreting androgenic hormone. At other times also this type of growth may be produced if gonadotropic hormone is simultaneously administered, so that at least two factors seem to be involved.

Thus, in carcinogenesis we have a biological phenomenon which may be attributed to a variety of different substances and agencies. This is by no means unique, for the same is true of other biological phenomena; but it is a circumstance which adds to the difficulty of interpreting the biological properties of the carcinogenic compounds and in estimating their ultimate significance.

OBITUARIES

Prof. Sydney J. Hickson, F.R.S.

By the death of Prof. Sydney J. Hickson on February 6 at Cambridge, British zoology loses one of its most distinguished professors. He was born in 1859, and was at Manchester from 1894 until 1926, during which he was identified with every aspect of the development of the University of Manchester. At the same time he annually contributed to the store of knowledge not only by his special researches on the soft corals, but also by investigations relating to water supplies, hospital sanitation, poultry and many local questions.

Hickson was the youngest of a family of nine, most of the older boys of whom were absorbed into the family manufacture of boots and shoes, then situated within the City of London. His parents were of Unitarian stock with advanced social views, and among their visitors he recalled Mrs. Besant, Charles Bradlaugh, Auberon Herbert, Charles Voysey and G. T. Holyoake, the last person in England to be sent to prison for blasphemy. This early intercourse left a permanent impression, and Hickson always remained an advanced Whig in public affairs, taking a particular interest in the Land Values League of Manchester. In contrast he was an 'out and out' Tory in his ordinary life, and a friend recalls his top-hatted, athletic figure on its morning walk from Withington to the laboratory.

Hickson's early education was at the Mansion Grammar School at Leatherhead, a beautiful old domain on the River Mole. Here he followed his brothers and acquired a taste for Nature, as Ray Lankester had done at the same school. In 1893 he entered University College School, passing on to the College in 1876, where he was so enthralled by Lankester's lectures—the courses commenced at 8 a.m.—that the following year he was Gold Medallist. Then he went on to "Barts", but he found conditions "indescribable and terrifying", Klein's course on histology being to him their one redeeming feature. Lankester advised Cambridge, and there in the laboratories of Michael Foster and F. M. Balfour he found his vocation and made many friends, Sedgwick, Haddon, Bullen, Caldwell, Threlfall and many others. He obtained a first class in the Tripos of 1881; but he had already, by dissecting, teasing and the use of the sliding microtome, begun his laborious studies of the eyes of Pecten and Spondylus; each section was removed and mounted separately by hand, for Threlfall had not yet made his automatic microtome. Similar technique was also employed for his now classical research on "The Eye and Optic Tract of Insects", 1885.

In 1882 Hickson became demonstrator to Moseley at Oxford. His interests henceforth were mainly marine and directed towards those sedentary forms of life upon which his professor had done such brilliant work. He was in Celebes for a year, much of it camped on the shore of Talisse Island ; but illness drove him to the higher lands of Makassar, where he studied native life. His results are published in "A Naturalist in North Celebes", which is distinguished by its vivid descriptions of shore life. In 1888 he was deputy professor at Oxford and in the next year accompanied his uncle, Sir Sydney Waterlow (formerly Lord Mayor of London) on a year's tour of Canada, United States and Mexico. In 1890 he returned to Cambridge as lecturer in advanced zoology. Gadow, Harmer and Shipley were his colleagues in these courses—a highly distinguished team, with Sedgwick to lead them. Each lecturer had his own technique and they were equally successful, for each allowed full play to his own psychology. Hickson was the most vivacious. There were gaps in anatomy, relationships and evolution ; but his beasts were 'alive and kicking', to his pupils' obvious interest and enjoyment.

Hickson became Beyer professor of zoology at Manchester in 1894, and to the regret of his friends his gaiety was largely eclipsed by that load of executive cares which are inseparable from the life of a professor of science. He succeeded Milnes Marshall, a brilliant zoologist, but a new broom has always dust to sweep away. A complete reconstruction of the course for medical students was necessary and teaching collections were deficient. The professors repeated their lectures and practicals to strictly segregated women students, and Hickson's refusal to do so brought about the necessary reform. At this time general interest in nature study and in science in schools was almost negligible in this busy commercial part of England. The new professor recognized this as a serious detriment to university work and set himself to remedy it, especially advocating nature teaching and school museums. Indeed, Lancashire's high position in these respects is largely due to Hickson and the public-spirited men who struggled to remove the financial difficulties which separated the schools from the universities.

The newspapers contain reports of numerous open lectures, especially in connexion with the Manchester Museum, and addresses to 'brotherhoods', excursions and discussions. The City Microscopical Society was his especial interest, and in his turn he was president of the Literary and Philosophical Society. He was a protagonist for the woman students, and the creation of their hall, athletic and other activities was largely due to him ; but perhaps he found the most fertile place for his ideals in the development of the Manchester High School for Girls.

On Saturday afternoons Hickson was always to be found on the University Athletic Ground, of which he was the permanent treasurer, often in summer handling a bat. At the same time he was active in all that concerned the governance of the University, being noted for his 'wise' opinions both on the Council and as dean of the science faculty. The growth and happiness of the University was greatly helped by that tradition of hospitality among its professors which his wife loved to foster, little dinner parties followed by good conversation, always humorous. In science it was a distinguished professoriate, including Alexander, Rutherford, Weiss, Elliot Smith, Dixon, Stopford (now vice-chancellor), Perkins, Lamb, Boycott, Reynolds, Loraine Smith and Hopkinson as vice-chancellor.

In 1895 Hickson was elected to the fellowship of the Royal Society, mainly on a series of papers elucidating the relationships of the soft corals (Alcyonaria). These became his chief theme of study for the rest of his life and he was universally recognized as the chief authority on them. His last paper dealt largely with the effect of symbionts and is now in the press. They were, too, the subject of his addresses as president of Section D of the British Association in 1903 and as Croonian lecturer of the Royal Society in 1916. In 1926 he retired to Cambridge. His mornings were devoted to his research, which, if anything, showed increased mastery, while his afternoons enabled him to display one of the best-kept and varied of small gardens, so different from his Manchester essays in horticulture. He was happy in the past and the present, cared for by his wife, who had been his pupil in his earlier Cambridge days. They had two children, one of whom is a child-specialist at Manchester, while the other, as secretary of the Extension Board at Cambridge, pursues an objective which his father at Manchester advocated forty-five years ago.

J. S. GARDINER.

Mr. E. N. Nevill, F.R.S.

MR. EDMUND NEVILLE NEVILL died on January 14 at his home in Eastbourne at the age of ninety-three. His contributions to science were in astronomy, and his first paper in the *Monthly Notices of the Royal Astronomical Society* appeared in June 1873. This paper was entitled "Note on the Possible Existence of a Lunar Atmosphere", in which he suggested that observations of occultations did not disprove the existence of an atmosphere on the moon. Altogether he contributed about fifty papers to the Royal Astronomical Society and until 1888 he wrote under the name of Edmund Neison, after which he reverted to his family name in accordance with the terms of a will.

Although most of Nevill's work was associated with problems in dynamical astronomy, in particular with those connected with the motion of the moon, he carried out observational work as well. In 1876 his well-known book, "The Moon and the Conditions and Configurations of its Surface", was published, and ten years later he brought out a work with the title, "Astronomy, a Simple Introduction to a Noble Science". Among his numerous contributions to the Royal Astronomical Society may be mentioned an important paper in November 1878 which showed that ancient eclipses indicated a greater value of the moon's secular acceleration than the Arabian observations suggested. He showed that it was possible to effect a reconciliation by postulating a term with a period of one to two thousand years and a coefficient three or four times that of Hansen's, and he expressed doubts regarding the existence of tidal retardations in the rotation of the earth. In a number of other papers he dealt with similar subjects, showing the presence of terms in the moon's motion due to the direct action of the planets, the value of the long inequality due to the disturbing action of Mars, lunar perturbations arising from Jupiter, etc. In the last point he was many years ahead of all other workers in the same field. His research in dynamical astronomy was not confined to lunar work and his versatile mind was able to turn to other branches. As one example, reference may be made to an important paper in 1879 with the title "On the General Solution of the Problem of Disturbed Elliptic Motion". An example of his interest in observational astronomy is shown by his work with a Newtonian reflector of 9⅓-inch aperture on the satellites of Saturn. He communicated his results to the Royal Astronomical Society in 1876 and dealt with his observations of Titania and Oberon, which he was just able to observe under favourable conditions.

In 1882 Nevill went to Natal to observe the transit of Venus, and as a result of the interest aroused in astronomy, a semi-public observatory was established through the generosity of certain residents in Durban assisted by the Corporation. Later, when this was taken over by the Government of Natal, Nevill was appointed the first director. Not only did he carry out the ordinary routine work of the observatory, but he also conducted research in his favourite subject and deduced new values for lunar elements. Reference has been made earlier to the results of some of this research. Unfortunately many of his results, including his lunar tables, still await publication. After his retirement from the observatory he does not appear to have done very much work, and the last paper that he contributed to the *Monthly Notices* was in May 1915 entitled, "On the Conjunction of Stars with the Moon, recorded by Ptolemy". He was elected a fellow of the Royal Astronomical Society in 1873 and a fellow of the Royal Society in 1908.

Mr. B. D. Porritt

THE death of Mr. B. D. Porritt, on January 28, came as a shock to his friends despite the long illness that had foreshadowed it.

Mr. Porritt was born of Yorkshire parents in Canada in 1884, and was educated at the Whitgift Grammar School, Croydon; at University College, London, where he graduated in chemistry in 1908; and at Heriot Watt College, Edinburgh. He joined the North British Rubber Co., Ltd., where he was chief chemist in 1912 and research superintendent in 1916. He left the Company in 1920 to assume the directorship of the Research Association of British Rubber Manufacturers, then inaugurated under the co-operative research scheme of the Department of Scientific and Industrial Research.

The chemistry and physics of the rubber industry in 1908 was much more primitive and ill-informed than to-day, and Mr. Porritt had a wealth of problems before him from the beginning. In the early years, he made useful contributions to analytical and testing methods for rubber. This interest continued throughout his life, for in later years he concentrated an enormous amount of fine detail work on the standardization of testing methods, and was a leading spirit in establishing the Rubber Industry Committee of the British Standards Institution.

Observations of a more fundamental nature were made, as early as 1920–21, on the then unsuspected photopolymerization of rubber solutions, and on the role of oxygen in the mastication of crude rubber. Both these subjects have since received much development in other hands.

Another early interest, which he was able to pursue at length for himself, was the study of the surface breakdown of hard rubber under the influence of light. He contributed also many observations on the swelling of rubber in non-aqueous liquids and on the factors influencing that obscure phenomenon. One of his last interests was the production of crude rubber in the form of fine powder, and the utilization of the new product in novel processes.

By way of a hobby, Mr. Porritt was the British rubber industry's historian, and his "Early History" has long been the classic source for all subsequent writers in this particular field.

The story of B. D. Porritt would be quite incomplete without stress being laid on his tireless work in promoting co-operative research. He commenced in and with the Rubber Research Association when the industry's interest was so lukewarm that only fifteen member firms supported the idea; he left it at his death with more than 170 member firms. This progress and success was due mainly, if not wholly, to his untiring efforts in promoting the co-operative principle, and to the sound work of the organization which he built up. His flair for organization, indeed, extended in many directions. He made a notable success of the Rubber Exhibition at the London Science Museum in 1934–35, and was a leading promoter of the Rubber Technology Conference of the Institution of the Rubber Industry in 1938.

He was author of a small book, "Chemistry of Rubber", in 1913, and co-author of the now well-known reference handbook, "Rubber, Physical and Chemical Properties", in 1935.

T. R. DAWSON.

WE regret to announce the following deaths:

Mr. K. E. Heesom, inspector of mines, Sierra Leone, on February 11, aged forty years.

Prof. J. H. Michell, F.R.S., professor of mathematics during 1923–1928, and honorary research professor of mathematics since 1928 in the University of Melbourne, on February 3, aged seventy-six years.

Prof. E. Soler, emeritus professor of theoretical geodesy in the University of Padua, vice-president of the International Association of Geodesy, on January 24.

Prof. Margaret Floy Washburn, professor of psychology at Columbia University, author of "The Animal Mind", aged sixty-eight years.

NEWS AND VIEWS

American Association: New President

DR. ALBERT FRANCIS BLAKESLEE, director of the Carnegie Institution Station for Experimental Evolution, Cold Spring Harbor, U.S.A., has been elected president of the American Association for the Advancement of Science. This election will be welcomed all over the world, because he has a high reputation as a botanist and as a pioneer in more than one line of research, while his genial manner and ever-ready help to all scientific workers are very well known. His early work, in which he showed that only individuals of a fungus species which were physiologically different could take part in sexual union, initiated a large number of investigations into the behaviour of sexuality in the fungi.

Later, in collaboration with a number of workers he had attracted round him, Dr. Blakeslee analysed the cytogenetics of the thorn-apple, *Datura Stramonium.* The discovery of secondary and tertiary trisomics, and the analysis of their constitution by Blakeslee and Belling was a turning point in modern genetics. Studies of tetraploid segregation in Datura, the production of many haploids and novel chromosome types and the analysis of the effect of changes in the chromosome constitution of a plant by Blakeslee are established as classical reference material. More recently he has been a leader in the utilization of colchicine treatment in the production of polyploid forms. Results of economic importance are already being produced, while a neat use of colchicine is being made for the elucidation of sex-determination in plants. Dr. Blakeslee's wide interests are appropriate to the presidency of the American Association.

University of Cambridge Parliamentary By-election

THE recent by-election in the University of Cambridge to choose a successor to the late Sir John Withers in the House of Commons was of unusual personal interest to scientific workers in that the two candidates must be well known to many of them. Prof. A. V. Hill, Foulerton research professor of the Royal Society, formerly Jodrell professor of physiology in University College, London, has been one of the secretaries of the Royal Society since 1935. Prof. John A. Ryle, regius professor of physic at Cambridge since 1935, has had a distinguished medical career in London, and recently completed a four-year term on the Medical Research Council. Both candidates adopted the adjective 'independent', and while Prof. Hill accepted the support of the Cambridge Conservative Graduate Association, Prof. Ryle preferred to style himself 'progressive'. Prof. Ryle's advantage as a Cambridge resident was offset by the fact that Prof. Hill, as a former scholar and fellow of Trinity College, is well known in Cambridge.

The result of the poll was declared on February 24: Prof. A. V. Hill, 9,840 votes; Prof. J. A. Ryle, 5,386 votes. Prof. Hill therefore goes to Westminster as one of the Parliamentary representatives of the University of Cambridge. In his election address, he claimed the independence usually accorded to university members; in addition, he stressed the importance of international co-operation in attacking the problems which will face the world at the conclusion of the War. He also urged the need for bringing science and learning to bear on national affairs, and said that "science has still too little influence on higher policy in government, in departments and in industry". As regards the universities, their strength must be maintained; industry will require new methods and materials in the recovery phase; improvements in public health must be studied; trained and critical young minds will be needed to meet the problems of reconstruction; and finally, the "free pursuit of knowledge for its own sake must be kept up". Prof. Hill's programme is comprehensive, but no one who knows him will doubt that he will press his views at the proper time with skill and vigour.

Heinrich Wilhelm Matthias Olbers (1758-1840)

ON March 2 a century ago, the city of Bremen lost its most distinguished citizen, the physician and astronomer Heinrich Wilhelm Matthias Olbers, who died at the age of eighty-one years, after a life of unremitting industry. He was born on October 11, 1758, at the village of Arbergen, near Bremen, where his father was pastor, and from his boyhood he was an enthusiastic student of science. When nineteen he became a medical student at Göttingen and at twenty-three set up in practice in Bremen. A conscientious practitioner, he served his fellow-citizens in many ways, and after his death his statue was erected in the city. His astronomical work was done in the upper part of his house in the Sandgasse, which was fitted up to afford a view of the greater part of the sky. His instruments included a 5-ft. Dollond refractor of 3¾-in. aperture, a 5-ft. reflector by Schröter, a quadrant by Bird and a Troughton sextant. It is said that he never slept more than four hours at a time.

Olbers is chiefly remembered for his discovery of asteroids and his fifty years' study of comets. In 1772 Bode had discovered the law of planetary distances bearing his name, and when in 1781 Herschel discovered Uranus it was concluded that there was a planet between Mars and Jupiter, and largely through Von Zach, in 1798 a party of astronomers met at Gotha to start a search for it. Another meeting took place at Schröter's observatory at Lilienthal, and zones of search were assigned to twenty-four astronomers. One of these astronomers was Piazzi of Palermo, but before instructions reached him, on January 1, 1801, he discovered the minor planet Ceres. The search being continued, Olbers, on March 28, 1802, discovered Pallas, on September 1, 1804, Harding discovered Juno, and on March 29, 1807, Olbers discovered Vesta. The fame of Olbers spread far and wide. He represented Bremen at the baptism of Napoleon's son the King of Rome in 1811, and during 1812–13 was a member of the legislative body in Paris. The Royal Society elected him a foreign member in 1804, and the Paris Academy of Sciences in 1829 made him a foreign associate. He was the correspondent of nearly every astronomer in Germany, and through him Bessel became known in the scientific world. Indeed he declared that his discernment of the genius of Bessel was a greater service to astronomy than his own work on comets and planets. He was a man of lovable disposition, generous and unassuming.

Laurent Théodore Biett (1781-1840)

DR. LAURENT THÉODORE BIETT, a celebrated Paris dermatologist, was born in 1781 at Schams, in the Grison canton of Switzerland. Seven years later he moved with his parents to Clermont-Ferrand, where he commenced his medical education under Bonnet, the senior surgeon to the Hôtel Dieu. At the beginning of the century he came to Paris, where he qualified in 1814 with a thesis entitled "Quelques Observations sur la frénesic aiguë idiopathique". Shortly after qualification he was appointed physician to the Hôpital Saint Louis, where he carried out some important improvements, including the establishment of an out-patient department for diseases of the skin, of which he was the director for sixteen years. While attending a patient in London in 1816, he took the opportunity of studying the work of Willan and Bateman, and on his return to Paris endeavoured to introduce their classification of skin diseases, which was in opposition to that drawn up by his friend Alibert.

Biett made many valuable contributions to the treatment of skin diseases, including the use of iron and arsenic internally, the employment of sulphur baths and the application of dry and hot air. His lectures, which were edited by Cazenave and Schedel, appeared in 1828, went through three editions, and were translated into English in 1842 by T. H. Burgess. He also contributed many articles to the "Dictionnaire des sciences médicales", and all the articles on diseases of the skin to the twenty volume "Dictionnaire de médecine", in addition to papers in periodical literature such as the *Bulletin de Thérapeutique*, *Gazette des Hôpitaux* and *Journal universel des sciences médicales*. Being a devotee of the arts, he was the medical attendant of many well-known painters, sculptors and actors. He died of heart disease on March 3, 1840.

Colonial Development and Scientific Research

PUBLICATION of the recommendations of the West Indies Royal Commission together with the important statement of policy on colonial development and welfare (H.M. Stationery Office. Cmd. 6174, 6175), to which Mr. Malcolm MacDonald, H.M. Secretary of State for the Colonies, made reference in the House of Commons on February 20, mark a momentous enlargement in scope in the administrative and financial relations between Great Britain and her colonial and other dependencies of analogous status which will have a profound effect on their future. The measures which the Government now proposes after an examination of Colonial problems which had been begun sometime before the outbreak of the War is an acceptance of an obligation which has long seemed inevitable to those who have been engaged in the scientific investigation of conditions in these dependencies if Great Britain's responsibility is to be met.

In brief, the proposals are as follow : The place of the Colonial Development Fund, instituted in 1929, and limited to a sum of £1,000,000 a year, will be replaced by a greatly increased provision for development and welfare. The sum will amount to not more than £5,000,000 a year for a period of ten years, at the end of which period this provision is to be reviewed. The amount thus made available, is not, however, from one point of view the most important enlargement. On one hand, assistance will no longer be granted, as hitherto in the main, solely to capital expenditure, but recurring expenditure will come under this provision. On the other hand, while certain purposes of expenditure have not been ruled out in terms, assistance has been granted generally to material development. In future this will not obtain ; and such services as agriculture, health, education and housing will be brought into the account.

Nor are the claims of the important question of research overlooked. Hitherto, as Mr. MacDonald pointed out, the Colonial Office has been able to call upon the assistance of scientific and technical experts in dealing with Colonial problems. This service will now be placed upon a permanent basis by the institution of a Colonial Research Advisory Committee, while for dealing with its recommendations a sum of £500,000 a year will be allocated. This will be used to assist in the various fields of research. As already mentioned, these proposals apply not only to the Colonies and Protectorates, but also to the Mandated Territories. The pause, which, as Mr. MacDonald intimated to the House of Commons, must ensue before they can come into full operation, will give the necessary breathing space for the careful preparation of plans.

Tibetan Coronation

IT is perhaps not surprising that, even amid other and insistent preoccupations, the accounts of the final act of the installation of the new Dalai Lama sent by correspondents to the world's daily press, have created a profound impression. Nowhere else, except possibly in Japan, could the inauguration of a new head of the State have so closely wedded the spiritual and the political and civic elements in what is virtually an act of coronation, and at the same time united every member of the population in an expression of combined loyalty and religious fervour.

Throughout the pageantry, the wealth and splendour of display of personal adornment, dress, and equipment vividly described in, for example, the dispatches of the correspondent of *The Times* in the issues of February 23 and 24, there is apparent an all-embracing current of mystic symbolism which endues every act, every movement and every attendant circumstance with the significance of worship, and of recognition of the spiritual influence which centres in and emanates from the person of the reincarnated head of the Tibetan spiritual and political hierarchy. It is this, and not the fact that such ceremonial has not been enacted in Lhasa for the space of sixty years, which animated the crowds through which the Dalai Lama was carried in his golden palanquin to the Potala, and on the following day added a solemn meaning to the blessings of a child conferred on the elders of church and State and later sanctified what was otherwise an unseemly scramble for the Dalai Lama's food as a re-enactment of the ancient ritual of sharing in the flesh of the sacrificial victim.

Relics of the Buddha

BUDDHISM of another order, but nevertheless of a closely related world of thought, appears in the announcement that Buddha relics of exceptional sanctity, discovered in Central India nearly ninety years ago and since in private possession in England, will now return to the East. They have been given to a Buddhist Temple in Ceylon by Mrs. Leslie Smith and Mrs. Winifred Burrows, granddaughters of General F. C. Maisey, by whom they were discovered when with Sir Alexander Cunningham he was investigating the numerous Buddhist monuments around Bhilsa in 1851. The discovery, as described in *The Times* of February 27, consisted of a relic casket—a small crystal tope, with terrace, plinth, hemispherical dome, square pedestal and a double pinnacle, this last forming the stopper of a small perpendicular shaft. This casket has been dated at about 350 B.C. The relic chamber at the bottom of the shaft contained minute pieces of bone, the whole being enclosed in a red earthenware box, which also contained other pieces of bone, and a series of the seven precious things usually accompanying the relics of an eminent person, namely, thin round pieces of gold, a bead of garnet, a crystal bead, two beads of pale greenish crystal, and some minute fragments of pearl.

The casket is now in the India Section of the Victoria and Albert Museum, South Kensington; but a cast and photographs have been supplied by the authorities in order that a replica may be made in Ceylon by native craftsmen. The relics and the seven precious things, which were retained by General Maisey when he presented most of the antiquities to the Museum, have now been enclosed in a carved silver tope from Ceylon for their conveyance to the island.

Sutton Hoo Burial a Cenotaph?

IN an account of the excavation of the Sutton Hoo ship-burial and of the associated antiquities delivered before the Society of Antiquaries of London on February 22 (see NATURE, Feb. 10, p. 231), Mr. C. W Phillips referred to the remarkable feature of the deposit that it did not accompany a body. The explanation which he put forward on certain grounds was that the mound and its contents as a whole had the character of a cenotaph for a great man whose body could not be recovered, possibly through being lost at sea. One suggestion which has been offered. namely that it may have been a measure of insurance on the part of a recently Christianized pagan in an endeavour to make the best of both alternatives, is perhaps not to be taken seriously. Nevertheless survival of a pagan ritual, even in such an essential rite as burial, cannot be ruled out entirely; and it receives a certain amount of support from the archaic character of the ship, of which some further account was given.

The excavation of the ship was under the direction of Lieutenant-Commander J. K. D. Hutchinson of the Science Museum, South Kensington. It proved to be a remarkable vessel in the form of an open barge, clinker-built, keel-less, and propelled by at least thirty-eight oars. It was described as a development of a type already known to archaeologists, and, it may be supposed, of a type already archaic at the time of its burial. In its character as a royal barge, a comparison was instituted with the position of the royal yacht *Victoria and Albert* among contemporary shipping. This view would accord with the interpretation of the find which emphasizes its highly ceremonial nature. At the same time it may be recalled that ship models found by the Danish Thule Expedition to Greenland pointed to Norse ships still being in use of which the essential features had remained unchanged for a period of nearly six hundred years.

Cosmic Rays

THE twenty-fourth Guthrie Lecture of the Physical Society was delivered by Prof. P. M. S. Blackett on February 26. He took as his subject "Cosmic Rays: Recent Developments". He said that the most important discovery of recent years in the field of cosmic rays was the realization that the hard or penetrating component of the rays consists of particles of a new type, called mesotrons. This new particle has a mass intermediate between that of the electron and the proton and possesses the peculiar property of being spontaneously unstable. Its average life when at rest is about one millionth of a second, but when moving fast it lives longer—thus giving a nice verification of Einstein's principle of relativity.

The rays incident on the earth's atmosphere are of very great energy. Recent work shows that some of the rays have an energy certainly as high as one thousand million million volts. This is an astonishingly great energy, and it is probably not the limit. It is quite likely that rays exist with energy as high as a million million million volts or even more. Particles of such great energy have very peculiar properties. Instead of producing a narrow track of ionization a fraction of a millimetre broad like normal atomic tracks, they make a track many metres broad. This is deduced from relativity theory, but has not yet been verified experimentally. Great interest is attached to the 'spectrum' of the rays incident on the earth's atmosphere, since they should give some light on a possible origin for the rays. It is rather remarkable to find that the spectrum of the rays can be represented roughly by a simple power law over a range of energy of above a million to one. More precisely, the number of rays with energy greater than some given value is roughly inversely proportional to the square of the energy, over the energy range from a thousand million to a thousand million million volts. It can scarcely be doubted that this remarkable law must have some profound, but at present unknown, cosmological significance.

Fuel in Science and Practice

THE monthly periodical *Fuel in Science and Practice* has completed eighteen volumes since it was launched as a supplement to the well-known mining journal *Colliery Guardian.* It was established on the initiative of the Coal Research Club in order to provide a medium of communication for those interested in the scientific study of fuel, and coal in particular. It was the first journal of its kind in the English language and has proved very successful, the success being doubtless due in a large measure to the efforts of its first editor, the late Prof. R. V. Wheeler. The first number of the nineteenth volume has now appeared under the editorship of Dr. R. Lessing, who has been associated with the venture since its inception. This, it may be taken, will ensure continuity of policy. It will continue to aim at providing a clearing-house for the results of investigations and a bridge between the science and practice of fuel technology.

The Institute of Fuel has decided to adopt *Fuel* as its research journal for the benefit of its members who wish to be kept informed of the results of recent investigations into coal and other combustibles. The Coal Research Club, assisted by an editorial committee, will continue to direct its policy and ensure the maintenance of its old and successful traditions. It seems probable that the importance of fuel technology for some years to come will ensure a prosperous future for this journal. At the same time, it is pertinent to recall the unsatisfactory state of the documentation of science. While it appears relatively easy to publish journals containing interesting articles, the thankless task of publishing systematic abstracts is a growing burden the support of which meets steady reluctance.

Coal-Gas and Fuel Research at Leeds

PROF. D. T. A. TOWNEND, who succeeded Prof. J. W. Cobb as head of the Department of Coal-gas and Fuel Industries and Livesey professor in the University of Leeds, has now issued his first report, covering the session 1938–39, to his Advisory Committee. He takes an opportunity therein to pay a tribute to the late Prof. Smithells, who died during the term under review and who was a member of the Committee from the time of its formation. To him also was due, more than to any other man, the formation of the Fuel Department in the University and, a few years later, the establishment of the Livesey chair by subscriptions from the gas industry.

In the body of the report, Prof. Townend reviews in turn the varied activities of his department, which has developed in several directions, not only fuel and gas engineering, but also the cognate subjects of refractory materials and metallurgy, in both of which teaching and research have made much headway. A post-graduate diploma in fuel and refractory materials has been instituted along similar lines to those already given in gas engineering and in fuel and metallurgy. The first opportunity will be taken to give a more systematic course in chemical engineering, which is, in effect, so largely the subject of the departmental teaching. Research continues to be supported by the gas industry and the Iron and Steel Institute. Prof. Townend is continuing work on flame, which had engaged him in London, and independent research work carried out by the staff and students continues to be a marked feature of the departmental activity.

Modern Colour Printing

IN the *Electrical Review* of February 2, an illustrated description is given of some of the new equipment installed by Geo. C. Caster and Co., Ltd., commercial and colour printers, who recently transferred their works to Cromwell Road, Peterborough. In accordance with modern practice the factory has been set out on a single floor, with a planned layout for the speedy handling of work and an uninterrupted continuity of production. There is no shafting, and individual direct electric drive is employed on all machines. One of the large high-speed letterpress machines is a two-revolution Miehle capable of a maximum output of 3,000 sheets, 25 in. by 40 in., per hour. Another large two-revolution machine takes bigger sheets (30 in. by 40 in.) and can print 2,300 sheets per hour. For small sheets up to 13½ in. by 20 in. vertical Miehle machines are brought into service. These are specially suitable for high-class colour printing. A maximum of 4,500 prints an hour can be handled by each machine.

The use of a general lighting system of high intensity throughout the factory makes local lighting unnecessary (except under the machine boards). In the composing room an illumination intensity of 35 ft.-candles at the working plane is obtained with Benjamin reflectors, which are also used in the binding department to provide 10 ft.-candles. To facilitate the matching of ink colours, daylight reflectors have been installed in the machine department to give 14 ft.-candles.

The Achromatic Lens

THE contributions made to *Lychnos* during the last two years by Drs. N. V. E. Nordenmark and J. Nordstrom dealing with the invention of the achromatic lens and the part played by S. Klingenstierna, professor of mathematics at the University of Uppsala, in the process, have been issued as a pamphlet by Almquist and Wiksells, Uppsala, with an English summary. Many of the original documents bearing on the history of the invention are reproduced with illustrations. One of the most important is Ramsden's Royal Society paper of June 18, 1789, from which it appears that Chester Moor Hall had an achromatic object glass ground for him in 1732 or 1733 and that achromatic telescopes were made for him by the Strand optician J. Bird. The patent for the construction of such lenses from crown and flint glasses was taken out in 1758 by J. Dollond but no calculations were given, probably owing to the desire to keep the theory from other opticians. Klingenstierna worked out the theory, published it in the Transactions of the Swedish Academy in July 1760 and sent a copy to the Royal Society, which published it, although Dollond stated that it contained nothing which he had not done himself previously.

Early Agricultural Tractors

MR. R. H. CLARK, in the *Engineer* of February 2, under the title "Some Early Burrell Engines", recalls an almost forgotten chapter in the development of steam traction engines, built mainly for agricultural work. In 1846, James Boydell took out a patent for his "Endless Railway", and eight years afterwards patented improvements on it. His ideas were taken up by Charles Burrell and Co., a firm of country engineers established at Thetford in 1770, and in 1856 the first road locomotive was constructed embodying the principle of the "Endless Railway". The general arrangement of the traction engine was much as that familiar a few years ago, but each of the wheels, instead of running on the surface of the road or field, ran on a series of flat shoes which in succession were brought into position by links and pins attached to the wheels. There were six shoes to each wheel.

This arrangement of shoes allowed the engine to move over the roughest roads and over soft and marshy ground. One of the illustrations shows an engine drawing four two-furrow ploughs. In 1857 a Boydell engine drew a load of nearly 44 tons from Bury St. Edmunds to Woolwich Arsenal at an average speed of 3·1 miles per hour. The cost of transport was 2*d*. per ton per mile against 6*d*. if horses had been employed. Boydell engines were apparently being built up to 1868, when they were abandoned for engines with ordinary wheels.

Prevention of Diphtheria by Immunization

ABOUT 60,000 cases of diphtheria, chiefly among children less than fifteen years of age, are notified annually in England and Wales, with some 3,000 deaths. Yet it has been shown, particularly in certain cities in Canada and the United States, that by artificial treatment or immunization the disease may be practically banished. The Minister of Health has therefore issued an official memorandum urging that artificial immunization should be undertaken by county councils and sanitary authorities (Memo. 170/Med. H.M. Stationery Office. 1*d*. net). It is suggested that the immunization should be undertaken as early in the child's life as is practicable and should form an integral part of the work of child welfare centres. The Memorandum gives technical details of the procedure and of the various forms of diphtheria prophylactic used, and of the need for Schick testing after treatment to ascertain whether this has been successful.

Lice

THE Minister of Health has recently issued a "Memorandum on the Louse and How to Deal With It" (Memo. 230/Med., 1940). Its publication comes at an opportune moment, when experience of evacuation has brought the louse problem into prominence. In the event of serious air raids large bodies of people may have to be removed to other districts. This, in itself, is liable to cause the spread of lice to localities, or among people, previously free from infestation. Ample powers are available under the Education and Public Health acts for the application of suitable control measures, and it is to be hoped that public medical officers and other officials will do all possible to reduce what has long been a standing menace to proper living conditions. Copies of the memorandum may be purchased directly from H.M. Stationery Office, or through a bookseller, price 2*d*. net.

Vitamin E

REFERENCE was made in NATURE of December 16, 1939, p. 1008, to a solution of vitamin E now available commercially. Glaxo Laboratories Ltd. put on the market in 1933 capsules of wheat-germ oil extract (thirty times as potent in vitamin E as wheat-germ oil itself). The capsules were given the name 'Viteolin' in 1937. Viteolin was the preparation used by Currie and M'Gonigle in their published clinical trials which confirmed in Great Britain the value of vitamin E in the treatment of habitual abortion. With the availability of vitamin E as a chemical substance (tocopherol) each 'Viteolin' capsule has been standardized to contain the vitamin E potency of 6 mgm. of tocopherol, the potency clinically established as the desirable daily dosage.

Institute of Physics and Freedom in Science

THE Institute of Physics has sent the following letter signed by its president, Prof. W. L. Bragg, to the Polish Ambassador: "On behalf of the Board of the Institute of Physics I have to convey to you, and through you to your Government, the deep sorrow with which British physicists at home and overseas have heard of the forcible closure of the Institute of Physics in Warsaw, the dispersal of its eminent staff and the confiscation of its valuable equipment. Our sympathy goes out to our Polish colleagues in this interruption of their labours for the progress of our science, and in the tragic and unmerited hardships and perils which they are enduring. We look forward to the time, which we pray may not be far distant, when, restored to its former freedom, the Institute of Physics in Warsaw shall once again take its place among the great scientific institutions, and continue its work for the advancement of learning, and the welfare of mankind."

British Museum (Natural History)

IT has been decided that the British Museum (Natural History) shall be open to the public every afternoon from 1 until 5 p.m. beginning on February 28, and it is intended after Easter that the Museum shall be open all day from 10 a.m. until 5 p.m. Certain galleries only are available, and the present restrictions will continue to apply to the number of visitors and to the admission of children unaccompanied by adults.

The Department of Botany has received about seven thousand specimens as a result of an expedition to the Outer Hebrides (Lewis and Harris) organized during the past summer by Miss M. S. Campbell. Miss Campbell was accompanied by Dr. J. W. Campbell, Mr. C. V. B. Marquand, and Messrs. A. J. Wilmott, E. B. Bangerter and J. A. Crabbe of the Department of Botany. The collection is fully representative of the summer flora of the areas visited. Dr. R. Scott Russell has returned from a botanical expedition to the Karakorum Himalayas. The expedition, which would otherwise have continued into 1940, was cut short by the outbreak of war and only the collecting planned for 1939 was carried out. The number of gatherings made was 870, and the specimens collected have been left at Kashmir to be forwarded to the Museum later.

Earthquakes in Turkey

ACCORDING to a *Times* message, the final official figures for the Turkish earthquake of December 26 are 32,741 killed and 9,404 injured. It is also reported that it has been decided to rebuild Erzinjan slightly to the north of the old town and that construction is beginning.

Aftershocks of the earthquake still continue with considerable severity. Between 3 a.m. on February 21 and noon on February 24 another 300 people were killed, many more injured, and more than 10,000 head of cattle perished in addition to six villages being completely destroyed. The earthquakes commenced about 3 a.m. on February 21, and before 5 a.m. there had been eight severe shocks. The epicentres appear to have been near the village of Soysalli, near Kayseri in Central Anatolia, some 150 miles south-east of Ankara. Soysalli and three other villages were completely destroyed and the shocks were sufficiently intense to have been felt in eleven districts and many towns, including Ankara, Istanbul, Smyrna, Konya and Adana. On February 22 there were six more shocks and on February 23 and 24 the shocks continued with decreasing severity. In spite of the intense cold which still prevails in this part of Turkey, many people are preferring to live in tents.

Problems of the Industrial Scientist

A CONFERENCE on "The Problems of the Industrial Scientist" convened by the Association of Scientific Workers and the British Association of Chemists, will be held on March 9, commencing at 2 p.m., in the lecture hall of the Pharmaceutical Society, 17 Bloomsbury Square, W.C.1. All scientific workers and others interested are cordially invited to attend and participate. Prof. F. G. Donnan will be in the chair Mr. Hugh Linstead, of the Pharmaceutical Society, will open the proceedings with a general survey of the problems of scientific workers employed in industry. This will be followed by a series of short papers and discussions. At the conclusion of these discussions, Prof. J. D. Bernal will sum up the discussion as a whole, and the conference will then consider the possibility of adopting a 'programme' for scientific workers in industry. Similar conferences are being held at Liverpool, at 6.30 p.m., on March 4, at 5–6 Bluecoat Chambers, Liverpool, 1; Manchester, at 3.0 p.m., on March 16, in the Chemistry Lecture Theatre, the University; Birmingham, date to be announced later. Following the regional conferences, it is intended at a later date to hold a National Conference to review the data and resolutions resulting from them, and to decide on the final form of the 'programme' and on steps to be taken to work for its acceptance. Further information can be obtained from the Secretary, Association of Scientific Workers, 30 Bedford Row, W.C.1.

Announcements

THE British Association is arranging a conference on "Science in National and International Aspects", to be held at Reading during July 24–26. This will take the place of the ordinary annual meeting which would in normal circumstances have been held at Newcastle.

MR. ASA BINNS, until recently chief engineer of the Port of London Authority and now a consultant to the firm of consulting engineers, Messrs. Rendel, Palmer and Tritton, has been elected president of the Institution of Mechanical Engineers for the year 1940.

DR. LOUIS MARTIN, director of the Pasteur Institute of Paris, has succeeded General Sieur as president of the Academy of Medicine of Paris.

THE Council of the Royal College of Surgeons of England has undertaken to organize a library at the medical base in France for the use of the officers of the Royal Army Medical Corps.

THE Oxford Ophthalmological Congress will be held at Oxford on July 4–6. Prof. Le Gros Clark will deliver the Doyne Memorial Lecture, and there will be a discussion on "Emergencies and Complications of the Operation for Cataract".

THE Board of Education has just published a "Handbook of Suggestions of Health Education" (H.M. Stationery Office. 6*d*. net). The book is issued primarily for the benefit of teachers, and covers most aspects of health education, and incorporates recent advances in the science of nutrition.

ERRATUM. Letter by Dr. D. Roaf entitled "Energies of β-Particles from Uranium-X_2" in NATURE of February 10, p. 223, the numbers along the $H\rho$-axis in Fig. 2 should read: 0, 5000, 10,000.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

IN THE PRESENT CIRCUMSTANCES, PROOFS OF "LETTERS" WILL NOT BE SUBMITTED TO CORRESPONDENTS OUTSIDE GREAT BRITAIN.

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 351. CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Radium Treatment

SIR LEONARD HILL returns in NATURE of January 27, p. 151, to his statement "that we would be little the worse off if all the radium now buried in deep holes for security from bombing remained there", and seeks to make good this assertion by reminding us of some of the casualties of radiological practice. He has allowed these examples to stay in the forefront of his mind, instead of fitting them into the groundwork of experience, which every practising radiologist must do.

The dangers attending the use of radium and X-rays have been the concern of the X-ray and Radium Protection Committee for many years. No Committee can possibly safeguard a patient against an unskilful application of rays, but radiologists have striven to limit such dangers by making a real specialty of their subject; and there are at present five universities or kindred bodies in Great Britain which grant medical diplomas in this subject. The subject has, indeed, reached a status where its exponents can afford to ignore the rather baser charges in question, but the dis-service of Sir Leonard is to the public, who pay undue attention to his *ex cathedra* statements.

It is not true that the 15,000 patients (mostly cancer patients) who received radium treatment in Great Britain during the year 1938 had such treatment because of the vested interests of the medical public; the vast majority had radium treatment because it was considered the best available for them. It should be remembered that more than 90 per cent of the country's radium is held by big organizations, such as the Radium Commission, the King's Fund and the Medical Research Council; this is some guarantee that it is used by people of responsibility.

Sir Leonard would like to see "the use of radium or X-rays being reserved for one or two places in the body where surgical operation is very difficult". The publication "Medical Uses of Radium" has been issued yearly since 1922 by the Medical Research Council, and the Radium Commission has in recent years made annual reports on the results of treatment; from them the pertinent fact emerges that the medical profession continues year by year to treat various forms of cancer at many sites of the body, and there is a disposition to widen rather than restrict the field. As for radium in the boreholes, it is only right that the public should know that much of the radium put away for safety has now been brought into use for their treatment.

SIDNEY RUSS.

Barnato Joel Laboratories,
Middlesex Hospital,
London, W.1.

Feb. 6.

SIR LEONARD HILL writes, in NATURE of January 27, with reference to radium treatment and expresses a belief that "we would be little the worse off if all the radium now buried in deep holes for security from bombing remained there. . . ." This pessimism contrasts notably with the enlightened optimism of the article, in the same issue, written by Dr. John H. Lawrence, of the University of California, who is working with great opportunities at present lacking in Great Britain. Lawrence and his co-workers are pursuing "the possibilities of artificial radioactivity and neutron rays in cancer therapy until a more satisfactory answer to this problem has been reached". What we require in Great Britain is a well-organized radiological institute where the various possibilities of radiation can be developed and extended. It had always been my hope and ambition that such an institute would be founded as a memorial to Lord Rutherford, who was always wide awake as to the possibilities of radiotherapy and the proper means by which they could be furthered or achieved.

Sir Leonard Hill has collected a certain amount of gossip about radium and narrates a few cases of failure due to the misuse of radium which have come to his personal notice. To counterbalance his citation of deplorable failure, I could quote instances in my own experience where men with cancer of the throat, and elsewhere, have been treated by radium and returned in full health and happiness to their useful work and daily life.

It is admitted by all that the cause, prevention and cure of cancer have not yet been attained. In some cases, when early treatment has been given, there has been cure or palliation by three chief means, surgery, radium, X-rays. All three methods can be and have been grossly abused in some cases, but wisely applied in a vast number of instances. It is not proposed to abolish railway signals because a signalman has wrecked a train by pulling the wrong switch; the effort is made to improve the arrangement, to make it fool-proof, to have an efficient block system. Surgery is not condemned wholesale because of occasional deaths by incapacity, ignorance or carelessness. There have been deaths from dressings or swabs left in the wound. The wrong gas has been administered as anæsthetic. Overdoses of morphia have been given. A man can cut his throat with a safety razor. All such mistakes are no justification for complete disuse of the means employed.

It is, however, necessary to answer Sir Leonard Hill's ill-timed statement in a more positive sense, always remembering that while surgery has been under the guidance of men of high skill and intelligence for centuries—of men provided with every facility—on the other hand, both radium and X-rays are recent discoveries and naturally their applications to therapy are yet in their infancy.

A system of properly controlled and measured dosage, which can be repeated at will with exactitude, has scarcely yet been fully evolved. Certainly, in the past haphazard applications have produced deplorable results, but these are now avoidable in consequence of the research work already done on the proper direction of the radiation and on the determination of the magnitude of the dosage delivered to the growth and to the surrounding tissues.

Sir Leonard raises the question of the relative merits of radium and of X-rays and settles the matter to his own satisfaction with a positive assertion in favour of X-rays. In no part of the world has this difficult question yet been answered with sufficient scientific evidence to admit of certainty. The same uncertainty prevails as to the rival merits of X-rays of various voltages and wave-lengths. We may conjecture, but we cannot assert. Indeed these two important questions are forming part of an investigation by the Radium Beam Therapy Research under the Medical Research Council, and it is a matter for deep regret that this important work should be temporarily suspended by the exigencies of war.

Some of my well-informed friends point out to me that, in the case of cancer of the uterus, Wertheim's operation for the removal of the whole organ has been given up by surgeons throughout the world and replaced by the use of radium and subsequent wider irradiation with X-rays. This change was largely due to the influence of pioneer work done at the Curie Institute in Paris and Radiumhemmet of Stockholm. In fact, no sooner was the radium placed underground in September than gynæcologists implored that some of it should be made immediately available to save life and relieve distress.

In the case of cancer of the breast, both surgery and radiation are available, and it is a matter of expert advice to decide which is the better in a given case; always insisting on the importance of early and *correct* diagnosis. In carcinoma of the throat, treatment by the radium beam can be used without mutilation or loss of speech, and in cases too advanced for surgery. While surgery may be of some avail with cancer of the rectum and prostate, we have to admit with regret that all methods fail when the œsophagus or stomach is concerned. In less serious cases—such as skin and lip cancer—either surgery or radiation is effective, but most patients would prefer to avoid mutilation and scar by the simple and perfectly safe application of a few milligrams of radium, or its equivalent, for a few hours.

It is scarcely necessary to reply to Sir Leonard Hill's reference to those unfortunate girls, who licking radium paint from their brushes, accumulated radium in their system. Is it suggested that this is in the remotest degree connected with radium therapy? As to the miners' phthisis in the Joachimthal mines, it can unfortunately be matched with closely similar results in the gold mines of South Africa—a matter requiring the closest attention and medical research with a view to prevention and cure.

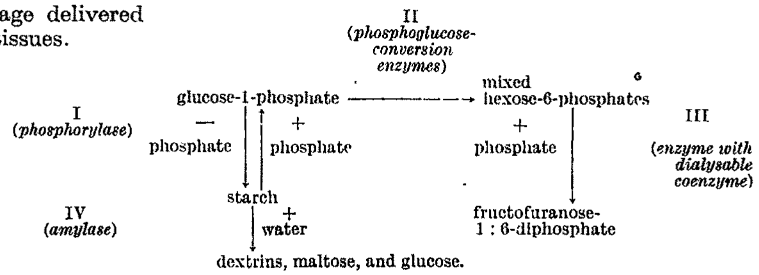
Feb. 5.

Enzymic Synthesis of Starch from Glucose-1-Phosphate

IN an earlier investigation[1] it was shown that pea seeds contain a complex of enzymes which catalyse the following series of reactions, I–IV:



II
(phosphoglucose-conversion enzymes)
glucose-1-phosphate
mixed hexose-6-phosphates
I
(phosphorylase)
— phosphate
+ phosphate
+ phosphate
III
(enzyme with dialysable coenzyme)
starch
IV
(amylase)
+ water
fructofuranose-1 : 6-diphosphate
dextrins, maltose, and glucose.

These transformations exhibit a striking parallelism with those associated with the breakdown of glycogen, and its recently reported synthesis from glucose-1-phosphate (Cori-ester), under the action of the enzymes of yeast[2], muscle[3] and liver[4].

In order to study in isolation the reversible reaction I it was necessary to obtain the phosphorylase free from the enzymes which catalyse the alternative reactions II and IV. This was achieved with extracts from pea meal by a process of fractional precipitation with ammonium sulphate.

Meanwhile it has been found that many plants contain phosphorylase, which is present in various organs including leaves, roots and tubers. The potato tuber has proved to be a particularly suitable source. Crude juice pressed from this tissue contains an active phosphorylase but exhibits no phosphoglucose-conversion activity; the weak amylase which is present is completely eliminated, and the phosphorylase is purified, by repeated fractional precipitation with ammonium sulphate.

Using these purified preparations of potato phosphorylase, a detailed study has been made of the reaction:

$$\text{Starch} + \textit{free}\text{-phosphate} \underset{b}{\overset{a}{\rightleftharpoons}} \text{glucose-1-phosphate.}$$

A state of equilibrium is reached, whether the reaction is proceeding in directions *a* or *b*, when the ratio of *free*-phosphate to glucose-1-phosphate attains a value which varies with the concentration of hydrogen ions. Thus in the equilibrium state at pH 6·4, 83 per cent of the phosphate exists as free-phosphate and 17 per cent as glucose-1-phosphate, whereas at pH 5·4 the proportions are about 90 per cent and 10 per cent respectively.

The equilibrium is not measurably affected by additions of starch even in considerable amounts, suggesting that the *effective* concentration of this reactant is not proportional to its *gross* concentration.

The presence of added starch, however, has a striking effect upon the velocity of the reaction proceeding in direction *b*. Without added starch there is a pronounced induction phase (in both the synthesis of starch and the liberation of *free*-phosphate). The initial velocity is increased by as much as 15-fold, and the induction phase completely abolished, by small additions of starch. This was the case in digests 1 and 2 (shown in Fig. 1), to which 2 mgm. soluble starch per 10 ml. was added initially. Other substances have been found to exert a similar activating effect upon the reaction, maltose being an example which has been investigated in detail. This phenomenon, which promises to illuminate the mechanism of the catalysis, will be considered fully elsewhere.

Several specimens of synthetic starch, about 20 gm. in all, have now been prepared from glucose-1-phosphate (purified by recrystallization of the potassium salt). The yields of polysaccharide corresponded closely in all cases with those calculated from the amounts of phosphate liberated, and amounted under appropriate conditions to twenty times the weight of dry matter in the enzyme. The principal difficulty in the purification of the synthetic starch has been the removal of protein; thus the precipitates formed on adding trichloroacetic acid or lead acetate contained the bulk of the starch; conversely, the blue-black flocculum formed by the addition of iodine contained much of the protein of the enzyme solution. The reason for this became clear when it was found by microscopic examination that, in advanced stages of the reaction when a marked turbulence develops, the starch is present in the form of small rounded granules which appear to be surrounded by loose floccules of protein; the starch grains are clearly visible whether or not they are stained with iodine (Fig. 2). Under the conditions so far used they attained a maximum diameter of 6–8 µ.

Various observations indicate that the synthetic polysaccharide is closely similar to natural starch. The main discernible difference lies in physical properties, the synthetic material being more resistant to solution and tending to retrograde more rapidly than natural starch of the common relatively large-grained varieties. The following are some of the analytical observations made on purified specimens:

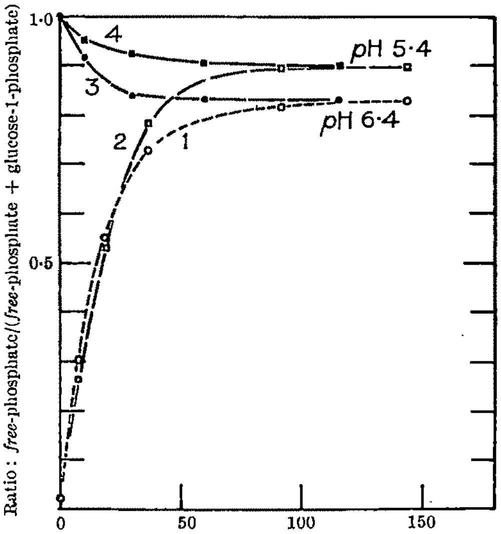


Fig. 1.

CURVES 1 AND 2 SHOW THE PROGRESS OF THE REACTION: GLUCOSE-1-PHOSPHATE → *free*-PHOSPHATE + STARCH, CATALYSED BY PURIFIED POTATO PHOSPHORYLASE; FINAL *p*H VALUES, 6·4 AND 5·4, RESPECTIVELY. CURVES 3 AND 4, AT THE SAME RESPECTIVE *p*H VALUES, SHOW THE REVERSE REACTION. IN DIGESTS 1 AND 2, APPROXIMATELY, *M*/100 GLUCOSE-1-PHOSPHATE WAS ADDED INITIALLY TO THE ENZYME, WHEREAS IN DIGESTS 3 and 4 STARCH WITH *M*/100 INORGANIC PHOSPHATE WAS ADDED.

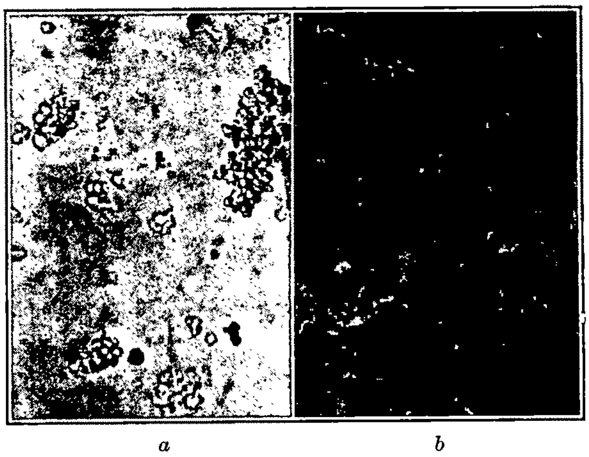

Fig. 2.

PHOTOGRAPHS SHOWING THE GRAIN STRUCTURE OF THE SYNTHETIC STARCH. *a*, UNSTAINED; *b*, WITH DILUTE IODINE. (× 290.)

Rotation—$[\alpha]_D^{20}$ + 200–206° (in water); + 152–159° (in 5 per cent soda); *Reducing power* (by copper reagent)—before hydrolysis, less than 1 per cent the reducing power of glucose; after 2·5 hours in *N*. hydrochloric acid at 100°—equivalent to 99 per cent conversion into glucose; nitrogen—0·05–0·5 per cent; phosphorus—0·05 per cent. In solution it gives a blue colour with iodine with the formation of typical iodine-starch floccules. The iodine-colouring property is rapidly destroyed by the action of the α-malt or salivary amylases.

The full discussion of the above interconversion, in which glucosidic linkages are formed and cleaved with the elimination and addition, respectively, of phosphate will be undertaken elsewhere.

The Nerve of the Pineal Gland

A BUNDLE of nerve-fibres running upwards from the tip of the pineal gland in some mammals was described by Kolmer and Loewy in 1922[1], and was termed by them the "nervus conarii". However, the existence of this nerve as a constant feature has not hitherto been generally recognized, and its origin and destination remain obscure. It has been described by Pastori[2] as having a terminal relation to the wall of the great vein of Galen (vena magna cerebri). Recently the nerve has been identified and studied in this laboratory in monkey and human material. In both cases it has been traced, in cleared preparations and in serial sections, following an uninterrupted course from the pineal gland along the vein of Galen to enter the dural wall of the straight venous sinus, where it runs in a subendothelial position.

In the human brain, the nerve passes through a remarkable formation of the arachnoid membrane. This resembles in some degree a greatly enlarged arachnoid granulation (Pacchionian body), measuring, in one specimen, 4·0 mm. in height and 2·5 mm. in width at its base. It projects up from the surface of the adjacent part of the cerebellum into the floor of the straight sinus at the point where this is joined by the vein of Galen, and is here attached to the dura mater. The structure of the granulation is peculiar in that it is filled with a sinusoidal plexus of blood-vessels and several large inter-connecting blood-sinuses. The pial matrix is unusually dense, and the general appearance bears a close resemblance to erectile tissue. The real nature and function of this arachnoid formation are still uncertain, but its structure and disposition suggest strongly that it may play an important part in regulating the venous return from the ventricles of the forebrain through the vein of Galen. In a distended condition, the granulation would bulge up conspicuously into the floor of the straight sinus at its anterior end, in a manner which must presumably impede the venous flow.

The nervus conarii, in traversing the granulation, actually passes through the cavity of one of the blood sinuses, ensheathed here in a fine covering of pial tissue. It then runs directly from the summit of the granulation into the dura mater and, as already noted, turns backwards in the floor of the straight sinus. Its further course has not yet been followed. The direction of conduction in the nerve is not known ; the fact that in the monkey it can be traced to a core of neuropil in the centre of the pineal gland, in which are embedded numerous large ganglion cells of an autonomic type, suggests that it may be efferent with regard to the gland. On the other hand, most authorities are now agreed that true nerve cells are not a normal constituent of the human pineal gland. The nerve is accompanied by a small arteriole, but this vessel is considerably smaller than the nerve itself. Finally, it may be noted that neither the monkey nor the human material has provided confirmation for the existence of a ganglion at the tip of the pineal gland, as described by Pastori.

A detailed report of these observations will shortly be published.

Cannabidiol and Cannabol, Constituents of *Cannabis indica* Resin

IN a previous publication, Work, Bergel and Todd[1] described a method for the separation of cannabinol from *Cannabis indica* resin (hashish) of Indian origin as its crystalline *p*-nitrobenzoate. In the course of further work on hashish we have been able, through the co-operation of the Home Office (Drugs Branch), to examine a fresh specimen of the Egyptian drug. Application of the *p*-nitrobenzoylation process to the distilled resin from this material yielded a less soluble fraction consisting of cannabinol *p*-nitrobenzoate (in smaller amount than from the Indian drug) mixed with a second ester of much lower melting point. The latter was very difficult to separate and purify ; the free phenol obtained from it by hydrolysis was a yellowish resin which, in contradistinction to cannabinol, gave a positive Beam test (purple colour with alcoholic potassium hydroxide).

Adams, Hunt, and Clark[2] have recently described the isolation from American hemp resin of a substance, cannabidiol, yielding a *bis*-3 : 5-dinitrobenzoate, m.p. 106–107° ($[\alpha]_D^{27°} = -76°$). The similarity in colour reactions of cannabidiol and the above substance from the Egyptian resin was immediately evident, and conversion of the latter to its *bis*-3 : 5-dinitrobenzoate gave an ester m.p. 106–107° of which the analysis and optical rotation ($[\alpha]_D^{13°} = -76 \cdot 2°$) also agreed with those of the cannabidiol derivative ; there can be little doubt as to the identity of the two compounds. The molecular formulæ of cannabinol $C_{21}H_{26}O_2$ and cannabidiol $C_{21}H_{30-32}O_2$, together with their simultaneous occurrence in hemp resin, suggest a structural relationship between the two compounds, and preliminary chemical investigation seems to bear this out[2]. It would seem that, as regards these constituents, Egyptian hemp resin occupies a position intermediate between American resin, in which cannabinol seems absent, and Indian resin, from which cannabidiol has not yet been isolated, although it may be present in small amount.

The physiological inactivity of cannabidiol lends further colour to the view that the Beam test is not a specific test for the active principle in hashish. We have noticed for some time that our most active fractions (Gayer test[3]) from the Indian drug give no coloration with alkali.

From certain fractions of Indian hashish we have recently, by acylation with azobenzene-4-carboxylic acid chloride, obtained a crystalline ester, m.p. 117–118° (Found : C, 78·0 ; H, 7·5 ; N, 6·1. $C_{21}H_{31}O.OCOC_{12}H_9N_2$ requires C, 77·9 ; H, 7·6 ; N, 5·4), apparently derived from a monohydric phenol. Alkaline hydrolysis of this ester gives a resinous phenol which reacts negative in the Beam test and gives, like cannabinol and cannabidiol, a positive indophenol reaction. The constitution of this new substance, which we name *cannabol*, remains to be elucidated, but it seems probable that it is a partially hydrogenated cannabinol isomeric with cannabidiol. This would accord with a possible view of the biogenesis of these substances. Cannabidiol may arise by condensation of a terpene with a dihydric phenol ; cyclization would then yield cannabol, from which cannabinol could be obtained by dehydrogenation.

Further details of this work will be published elsewhere.

Polyploidy in *Rumex acetosella* L.

The species *Rumex acetosella* L. is a weed, which seems to be distributed all over the northern hemisphere. It has been investigated cytologically by Roth[1], who counted the chromosome number $n = 16$ ($2n = 32$), and later, among others, by Meurman[2], Kihara[3], and Jensen[4], who all found the number to be hexaploid or $2n = 42$.

Last summer I examined material of *Rumex acetosella* and its varieties from Sweden and Iceland. In the main species, having rather broad leaves, I also found the hexaploid number $2n = 42$, both in the male and the female individuals. However, in plants belonging to the variety *tenuifolius* A. and Gr. (Ascherson and Graebner[5]), the number proved to be $2n = 28$, or tetraploid. This number was not known before in *Rumex acetosella*, according to Tischler[6].

The leaves of the tetraploids are narrower than those of the hexaploid forms. In other details the tetraploid variety is also smaller than the main type, and most often shows a prostrate mode of growth. Both the tetraploids and hexaploids are quite normal sexually, and they also seem to have different geographical distribution.

Occurrence of Bismuthinite in Somerset

At the end of July last year, while examining the material on the waste-heaps of the Langham Hill Mine, one of the group on the Brendon Hills, Somerset, which was worked for iron during the middle and latter half of last century, I noticed small stains and patches of malachite on some of the crystalline chalybite at one end of the main dump. A number of these pieces were collected and, on being broken open, were found to contain small amounts of chalcopyrite, bornite, and occasionally chalcocite, while a few had, in addition, thin veins and patches of a steel-grey metallic mineral scattered through them, in some cases closely intergrown with the copper minerals.

Blowpipe tests on this steel-grey material showed the presence of copper and bismuth, and from its association with the other copper compounds, it was at first taken as possibly being tetrahedrite; recent chemical and X-ray examination, however, by Mr. F. A. Bannister, of the Mineral Department of the British Museum (Natural History), has proved it to be bismuthinite (Bi_2S_3).

The presence of small amounts of copper minerals at one or two of these mines has been previously noted and mentioned, but there is no record of bismuthinite being found on the Brendons before, and it is a somewhat unexpected mineral to come across in this particular district, or, in fact, in Somerset as a whole.

Points from Foregoing Letters

S. Russ comments on recent statements by Sir Leonard Hill on the present-day position of radium treatment. He affirms it is not true that this form of treatment is largely carried on because of the vested interests of medical men; the reason for 15,000 patients having been treated in 1938 is that it was considered by responsible medical opinion to be the best treatment available for them.

A. S. Eve also discusses Sir Leonard Hill's communication. He states that in cases of cancer of the uterus radium is frequently preferred to surgery. Inoperable cases of cancer of the throat are improved by radium beam treatment. The relative merits of radium and X-rays require further investigation, and the same is true of X-rays of various wave-lengths. Great Britain requires a radiological institute for the development and investigation of radiation treatment. In the meantime surgery, radium, X-rays all have their spheres of usefulness which overlap one another.

C. S. Hanes reports the occurrence in various higher plants of an enzyme which catalyses the reversible conversion of starch into glucose-1-phosphate. The effect of different factors upon the equilibrium is discussed, together with observations on the properties of specimens of starch synthesized from pure glucose-1-phosphate by the action of this enzyme. A fact of considerable botanical interest is that the synthetic starch is deposited in the form of well-formed grains.

W. E. Le Gros Clark states that the nerve of the pineal gland (nervus conarii) has been identified in human and monkey material. It runs an uninterrupted course from the tip of the pineal gland into the dura mater of the tentorium cerebelli, and then extends backwards in the floor of the straight venous sinus. On its way the nerve traverses a large arachnoid granulation the structure of which is peculiar in that it contains a plexus of sinusoidal blood-vessels. From the position of this granulation it is surmised that it may play an important part in regulating the venous return from the brain through the great vein of Galen.

The isolation of cannabidiol from Egyptian hashish is reported by A. Jacob and A. R. Todd, who find that in respect of its content of this substance and cannabinol the Egyptian drug is intermediate between the American and Indian varieties. A new compound *cannabol*, which is probably a partially hydrogenated cannabinol, has been obtained from Indian hashish.

RESEARCH ITEMS

Bronzes from Southern Nigeria

A REMARKABLE collection of bronze castings found at Igbo, Southern Nigeria, is figured and described by J. O. Field, assistant district officer, in *Man* of January 1940. They were unearthed in the course of digging a well, but no details are available. The castings would seem to have been made by the *cire perdue* process, though rubber latex may have been used instead of wax. The castings are covered with a rich green patina. The finest piece is an urn or cauldron 10½ inches high with a diameter across the top of 8 inches. It forms a shallow bowl with broad lip on a wide hollow stand. It is decorated with a series of rosettes interspaced with beetles and grasshoppers. At top and base are bands of hatched triangles and in the middle a broad band with a complicated design of rectilinear figures and circles. The edge of the lip and the base are decorated with a twisted cord design. Among other objects are two scabbards in which are the remains of iron blades, but without hilts, a bust with evidence of bead ornament, small shells which rotate, a human head, possibly female, showing cicatrization resembling the modern style, two highly conventionalized rams' heads, with highly ornate twisted horns and three spiral objects, of which two display a snake *motif*, while another peculiar object is a massive casting elaborately ornamented with eyelets, loops and whorls, and also extensively ornamented with coloured beads, and near the top a series of rings from which emerge small snakes' heads, having above them a wheel-like flange with a great number of triangular spokes and on top of this a wide metal ring. The occurrence of an 'Aro knot' suggests contact with the Aro people, but the earliest tradition of their presence in the region does not go back beyond about the middle of the last century. Otherwise there is nothing to determine the origin of this metal work. The Igbo people are not themselves metal workers, and it is improbable that they were made by Benin craftsmen.

Canoe-making in Ancient Hawaii

A TREATISE on the canoe-making profession of ancient times, of native authorship but undated, found among the archives of the Bernice P. Bishop Museum, Honolulu, has been translated and edited by Kenneth P. Emory and Mary Pukui (*Occasional Papers, Bernice P. Bishop Mus.*, 15; 1939). The writer opens with the statement that the profession was much practised in Hawaii to provide the canoes for fishing, for war and for voyaging from island to island, the experts who built them being much honoured and favourites of the chiefs. There were classes of experts under the classes of royal builders, such as the experts of the supreme ruler, of the ruling chiefs, of the district chiefs, and so forth. Of the timbers used, the koa (*Acacia koa*) was the best. All the forests were occupied by experts for making canoes. The adzes used were of stone. Their making was a laborious task, in which the various operations, chipping, grinding, lashing, were each done by different specialists. Different adzes were used for the various operations—chopping, hewing, hollowing. The canoe-makers were supplied with ancestral gods, who helped in the hewing and hauling. They were both male and female. The canoe-makers were also provided with offerings. If the canoe belonged to a chief these offerings were a hog, red fish, clothing, coconuts and awa. The hog was cooked at the place where the koa tree was to be found. The ancestral gods partook after an invocation, and then all the priests present partook of their portion. The cutting of the tree then began, the priests cutting in pairs. A little bird signified whether the tree would be good or the reverse. The canoe of a chief was hauled to the shore by the people after a feast. Felling the path of the canoe was the last thing to be done. If a new canoe was first taken on a fishing trip, the first fish caught was brought back and offered to the ancestral gods.

Birds of Newfoundland and Colour Modification

SURPRISINGLY little is known of the birds of eastern Newfoundland, and accordingly brief explorations made by David C. Nutt while a member of the Robert A. Bartlett Greenland Expeditions of 1937, 1938 and 1939, have added considerably to the knowledge of distribution, abundance and geographic variation. The results, by John W. Aldrich and David C. Nutt, have recently been published (*Sci. Pub. Cleveland Museum Nat. Hist.*, 4, 13; 1939). From a general point of view, the most striking result is the discovery that where geographic variation has taken place among resident birds it is shown in a marked darkening of the plumage. This was found, for example, in birds so different as a creeper, *Certhia familiaris*, robin, *Turdus migratorius nigrideus*, "the most deeply coloured of all the American robins", warbler, *Dendroica breviunguis*, water-thrush, *Seiurus n. noveboracensis*, crossbill, *Loxia l. leucoptera*, and others. A similar darkness of plumage was noted in 1919 by G. K. Noble in birds from the western part of the island, but in the east the deepening of colour is even more marked, and confirms Noble's opinion that Newfoundland is a region where the differentiation of dark coloured races is beginning to take place. It may be associated, as is probably also the case in the outer islands of Scotland, with the exceptional humidity of the region.

Transpiration into a Saturated Atmosphere

H. H. Dixon and J. S. Barlee have recently published a paper describing further experiments on transpiration into a saturated atmosphere (*Sci. Proc. Roy. Dub. Soc.*, 22, No. 20, 211; Feb. 1940). A potometer method for comparing the rates of transpiration in gases supersaturated with water is described, and it is shown that replacement of air with nitrogen around the leaves depresses and ultimately inhibits the upward movement of water in a stem. Renewal of the air restores transpiration. Anæsthetization with chloroform reduces or stops the movement; and at least temporary recovery may be attained by surrounding the leaves with supersaturated air. If the supply of supersaturated nitrogen or chloroform is prolonged, reversal of the upward current is produced, and the shoot behaves like a dead system and the water condensing on the leaves flows downwards in the stem.

Inheritance of Inability to Sweat

L. C. Glass and Darrell H. Yost (*J. Hered.*, **30**, 477–478 ; 1940) report the inheritance of the inability to sweat. The affected individuals show distress at above 85° F., are subject to severe headaches and stomach trouble. The pedigrees suggest that the character is either inherited as a monogenic recessive or on a multiple factor basis. Not only is there an absence of sweat glands in the skin, but also other anomalies of skin development are present.

Sweet Potato Breeding

The sweet potato rarely flowers or sets seed under field conditions in Louisiana. J. C. Miller (*J. Hered.*, **30**, 485–492 ; 1940) reports useful methods for the induction of flowers and seed under these conditions. By staking the plants, three varieties were induced to flower, while girdling trebled the number of flowers and also induced earlier flowering. Seed setting was considerably increased by keeping a flowering branch in a water solution of artificial fertilizers in a house.

Cytological Investigations in Allium

S. W. Mensinkai reports on the chromosomes of seventeen species of Allium, fifteen of which had not been previously reported. *A. sativum*, and *A. Cepa* ($2n = 16$) are taken to be secondarily balanced diploids since they possess two pairs of nucleolar chromosomes and two pairs of nucleoli. Univalents were observed at meiosis in *A. Cepa*, *A. Sewerzowii*, *A. nigrum*, *A. scorzoneræfolium* (all diploids) and *A Bidwelliæ* (tetraploid). The individuals examined of *A. Cepa*, *A. Sewerzowii*, *A. cilicum*, *A. scorzoneræfolium*, *A. nigrum* and *A. Bidwelliæ* were inversion heterozygotes.

Wound Hormones of Plants

Many plant tissue extracts are capable of inducing renewed growth activity in mature plant cells. These growth-inducing extracts are usually obtained from ground or heated tissues and are capable of evoking cell division and cell enlargement in unwounded cells. The active principles have been referred to as wound hormones by Haberlandt. J. English, J. Bonner and A. J. Haagen-Smit (*J. Amer. Chem. Soc.*, **61**, 3434 ; 1939) find that the crystalline substance isolated from string bean pods and capable of inducing renewed cell division and cell extension activity in the parenchymatous cells of the bean pod is 1-decene-1,10-dicarboxylic acid (which they propose to call 'traumatic acid'), which was also synthesized. This is capable of inducing wound periderm formation in washed disks of potato tuber and to function thus as a wound hormone. Traumatic acid is also capable of partially replacing the juice of the tomato fruit in reversibly inhibiting the germination of tomato seeds.

Synthesis of Vitamin K_1

L. F. Fieser (*J. Amer. Chem. Soc.*, **61**, 3467 ; 1939) has found that synthetic 2-methyl-3-phytyl-1,4-naphthoquinone is identical with natural vitamin K_1 by a direct comparison of samples with regard to analysis, spectrum, anti-hæmorrhagic activity, colour reaction, and the melting point and mixed melting point of a crystalline derivative. This confirms the conclusion reached by Doisy and co-workers from degradative experiments (*ibid.*, **61**, 2558 ; 1939) and from a further synthesis (*J. Biol. Chem.*, **130**, 433 ; 1939), published after the present work was completed. The synthesis was essentially a one-step process utilizing 2-methyl-1,4-naphthohydroquinone and phytol, and provides a method of preparing the vitamin in quantity. By separating and purifying the product in the reduced form prior to oxidation, the quinone is obtained in a pure condition without recourse to distillation or adsorption. Natural vitamin K_1 can be isolated very easily from alfalfa concentrates by a similar procedure. Vitamin K_1 yields phthiocol on cleavage with alcoholic alkali.

Oxidation with Lead Tetra-acetate

It is known that the cleavage of the carbon chain in compounds containing two and three adjacent hydroxyl groups can be carried out with lead tetra-acetate in aqueous as well as in non-aqueous solution. J. M. Grosheintz (*J. Amer. Chem. Soc.*, **61**, 3379 ; 1939) finds that the cleavage of the carbon chain of a number of glycosides with lead tetra-acetate is parallel to that known to be produced with periodic acid. The oxidative changes of alpha- and beta-methyl-*l*-arabinopyranosides can be carried out quantitatively in aqueous solution. Contrary to previous experience, three molecules of lead tetra-acetate instead of two were required to complete this reaction, and the reason was found to be the oxidation to carbon dioxide of one molecule of formic acid formed during the first reaction. This reaction does not occur in dry organic solvents or in oxidation in aqueous solution by means of periodic acid, and the formic acid may be oxidized in its ortho-form.

Photometry of the Solar *D* Lines

Although the *D* lines have been measured several times previously, there has always been some doubt about the instrumental corrections, more especially for the central intensity. In a recent paper (*Mon. Not. Roy. Astro. Soc.*, **100**, 1 ; November 1939), C. W. Allen gives the results of his measurements, corrections derived from a comparison with terrestrial water-vapour lines having been used. The sun telescope and three-prism spectrograph of the Commonwealth Solar Observatory were utilized for the solar spectra of the *D* region. Plates were taken of both centre and limb of the sun near midday, and others were exposed for a few minutes after sunrise to ensure strong water-vapour lines. The results for the central intensities and equivalent breadths are in good agreement with his observations made some five years ago, but the central intensities are much smaller than Houtgast's results published in 1938. The discrepancies are due to the fact that Houtgast made no corrections for finite resolving power.

An Altazimuth Mounting for Reflecting Telescopes

The Rev. W. Rees Wright has described a useful wooden mounting to carry a 9-inch reflector which he has manufactured himself (*J. Brit. Astro. Assoc.*, **50**, 3 ; 1940). The base of the stand is merely a stout three-legged stool, each leg being 30 in. long and 3 in. by 2 in. in section. The top consists of two thicknesses of 1-in. wood, screwed together with the grain crossing, and twelve ball-casters are screwed to the upper piece so as to form a circular bearing for the head. It is possible to raise or lower these casters slightly to make certain that all bear on the head in all positions. Many other details are given which can be easily followed by amateurs, who are recommended to study the description with the diagram if they require a cheap and efficient mounting for a small reflector.

FLORAL ANATOMY OF THE OLEACEÆ

BY PROF. A. C. JOSHI AND A. N. FOTIDAR,
BENARES HINDU UNIVERSITY

A STUDY of the floral anatomy of the Oleaceæ, including *Jasminum pubescens*, *J. Sambac*, *J. auriculatum*, *J. arborescens*, *J. grandiflorum*, *J. humile*, *Nyctanthes arbortristis*, *Olea cuspidata*, *O. fragrans*, *Syringa vulgaris*, *S. emodi* and Ligustrum spp., has brought to light many interesting facts, particularly with regard to the anatomy of the pedicel in Jasminum species and the vascular supply of the ovule. As the full work will take still some time to be completed, the more important observations made so far are recorded here.

The pedicel has normal structure in Olea, Syringa and Ligustrum. Even in *Nyctanthes arbortristis*, where the vegetative stem is characterized by the presence of four inversely orientated cortical bundles[1], the cortical bundles gradually disappear in the floral axis and it has a normal structure. In Jasminum species, however, the condition is very different. In *J. auriculatum*, *J. humile* and *J. arborescens*, the pedicel has normal structure, but in others the pedicel shows, besides the normal vascular ring, many additional bundles in the pith, even though the structure of the vegetative stem is quite normal. Thus in *J. pubescens*, we find that the pedicel just at its base shows only one ring of vascular bundles, but as we proceed upwards, two or three bundles of phloem make their appearance in the pith. Higher up, the number of such bundles increases and they develop both xylem and phloem, so that a transverse section of the pedicel shows many medullary bundles irregularly scattered inside the normal ring (Fig. 1). The structure of these bundles is very variable. They may be collateral, normally or inversely orientated, bicollateral, concentric with phloem in the centre, or may consist of phloem alone. As the calyx-traces begin to pass out, we often find the medullary bundles to show a more regular arrangement. They tend to form a ring of mostly inversely orientated collateral bundles to the inside of the normal ring (Fig. 2). This condition resembles to a certain extent the structure of the stem in certain species of Rumex belonging to the section Lapathum[2], or the structure of the stem of many Cucurbitaceæ[3] and other families possessing medullary phloem. At a still higher level in the thalamus of *Jasminum pubescens*, the medullary bundles gradually pass out and disappear, merging into the bundles of the normal ring. In a large-flowered variety, however, it was observed that all the medullary bundles ultimately fuse in the centre and give rise to a prominent concentric bundle in the centre of the thalamus stele (Fig. 3), which divides again into about four branches that fuse with the ventral traces of the carpels. The pedicel in *J. grandiflorum* shows structure very similar to that of *J. pubescens*, but the medullary bundles are still better

developed. The pedicel in *J. Sambac* also shows medullary bundles, but here their number is comparatively smaller and they consist mostly of phloem alone (Fig. 4). Their structure, however, is essentially concentric, the phloem being surrounded by a cambial ring which forms new phloem elements towards the inside and occasionally some xylem towards the outside.

Jasminum Sambac. TRANSVERSE SECTION OF THE PEDICEL NEAR ITS DISTAL END SHOWING MEDULLARY BUNDLES OF PHLOEM SURROUNDED BY CAMBIUM.

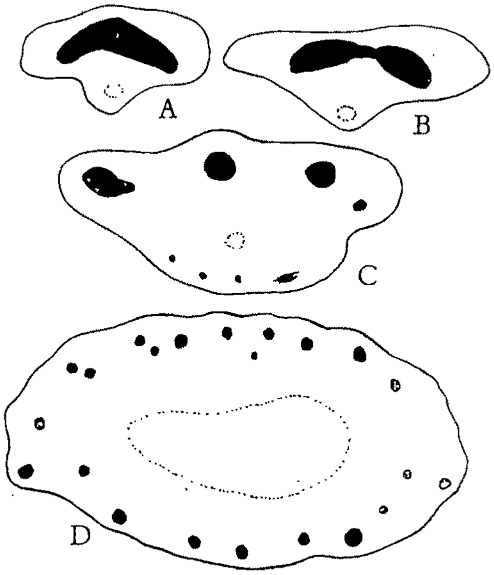

Fig. 5.

A–D. Nyctanthes arbortristis. TRANSVERSE SECTIONS OF AN OVULE FROM THE FUNICLE (*A*) TOWARDS THE MIDDLE (*D*).

The ovules of Syringa, Olea and Ligustrum species possess normal vascular supply. They receive a single bundle which runs up the raphe unbranched and ends in the chalaza. But in Jasminum and

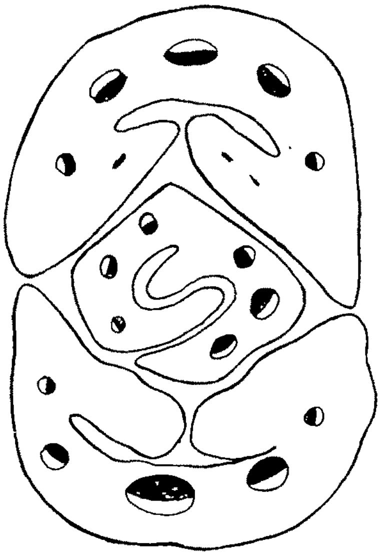

Fig. 6.

Olea fragrans. TRANSVERSE SECTION OF THE GYNŒCIUM SHOWING TWO DECUSSATE WHORLS OF OPEN CARPELS. THE OUTER CARPELS BEAR OVULES ALONG THEIR MARGIN. THE INNER CARPELS HAVE NOT YET COMPLETELY SEPARATED FROM ONE ANOTHER. AN OVULE IS SEEN ARISING FROM THE MARGIN OF ONE OF THEM.

Nyctanthes, the crescent-shaped ovular trace (Fig. 5*A*) soon after its entrance into the funicle divides into two bundles (Fig. 5 *B*). These bundles repeat the division and some of the branches pass to the opposite side (Fig. 5 *C*). These branches divide further, so that the ovule shows about its middle 25–30 bundles in the integument (Fig. 5 *D*). Such extensive development of the integumentary vascular system has been observed so far only in a few other flowering plants. These have been listed by Dahlgren[4]. From comparison with the gymnosperms, the presence of such an integumentary vascular system is generally regarded as a primitive character[5], but its occurrence in such gamopetalous forms as the Oleaceæ and the genus Echinops[4] of the Compositæ together with its absence from such a primitive order as the Magnoliales raises a doubt that this character may be really a recent acquisition related to the development of an exceptionally thick integument.

The perianth traces in the Oleaceæ are noteworthy for showing concentric structure, but specially interesting is the vascular supply of the calyx in *Olea fragrans*. In this species, although the calyx is quite well developed, in many flowers there are absolutely no traces for the four sepals. In other flowers, two or three weak sepal traces are given out, but these disappear in the thalamus itself and never reach the sepals. The calyx is thus quite non-vascular. This supports Mrs. Arber's[6] view that the vascular tissue is in no way more conservative than the organ it supplies.

The gynœcium of *Olea fragrans*, a cultivated garden shrub which does not set seed, consists of two whorls of opposite and decussate open carpels bearing ovules along their margins (Fig. 6). This abnormal structure of the gynœcium is the normal feature of this species in the material at our disposal.

RURAL LIFE IN EUROPE

By Dr. L. Dudley Stamp

It is one of the inevitable consequences of war that the steady march of social progress is interrupted by the more urgent problems of the moment. In Britain, for example, the great work of slum clearance and rehousing has been temporarily suspended, and it is actually possible in the lull to take stock of what has been achieved in the past twenty years. On the other hand, reforms which might have been delayed indefinitely may be rushed through if they have an important bearing on the prosecution of the War. The war-time ploughing programme of the Government may well be the salvation of British agriculture, and the evacuation to rural areas of both children and adults supplies just the stimulus which was needed to stem the tide of rural depopulation and the consequent disappearance of rural community life.

It is indeed certain that all the countries of Europe were becoming aware of the seriousness of the problems of rural life, and no fewer than twenty nations had agreed to take part in a European Conference on Rural Life—to be "devoted to the well-being and solidarity of the European peasantry"—under the auspices of the League of Nations at Geneva in October 1939. The Conference, a natural development of that on Rural Hygiene in 1931, was to have based its work on a series of documents previously prepared. The documents were of two main types: (*a*) illustrated national monographs, prepared officially according to a uniform plan, presenting in attractive style a résumé of the problems of rural life, and (*b*) studies on specific problems prepared by various international bodies.

Several of the national monographs were published[1]—including those for Belgium, Finland, Latvia, Lithuania and Netherlands—and form handy summaries covering the organization of rural life and occupations, including education, medico-social policy and nutrition.

Of the second group of pamphlets, the International Labour Office prepared one on recreation in rural areas and one on sickness and insurance; the International Institute of Intellectual Co-operation one on intellectual aspects of rural life, and the Health Committee of the League of Nations a general survey of medico-social policy. These surveys[2] suffer from the difficulty that they deal with political units so utterly different that comparisons are virtually impossible. The very word 'peasant' is rarely if ever applied to the English country dweller, and the problems here are obviously very different from those in eastern Europe. Nevertheless, it is remarkable that certain fundamental difficulties are apparent throughout—and outstanding is the inadequacy of rural housing. Cramped, overcrowded, ill-planned houses, frequently with antiquated sanitary arrangements, no piped water supply and lacking electric light not only affect health (for example, tuberculosis) but also prevent the proper use of leisure and opportunities for recreation and education which are otherwise available.

Rural housing is, after all, only one result of the fundamental economic position. A few years ago Lord Stamp[3] summed up the whole problem in a single sentence: "the world as a whole and over a given length of time has almost certainly been fed below cost-price for the last hundred years, if one takes into account the proper elements of costs". The more advanced nations are often the last to recognize that the rural countryside needs above everything money. Britain is certainly no exception; with the drift to the towns from the impoverished country areas Britain has become more and more urban-minded as well as urban-dwelling. The Town and Country Planning Acts only conceive 'planning' in terms of urban expansion, whilst slum-clearance is regarded as a problem of the great cities despite the fact that the worst slum is often the farm labourer's cottage.

PRACTICAL ASPECTS OF EARTHING

IN a paper contributed by Messrs. E. Fawssett, H. W. Grimmett, G. F. Shotter, and H. G. Taylor, to the Institution of Electrical Engineers on February 14, a very thorough discussion is given of the practical aspects of earthing.

The practice of earthing is as old as that of electrical engineering; in fact it is older, as it dates back to the days when electricity was only a scientific study which scarcely interested the engineer. Earthing was then effected by touching the charged body with the finger, whereupon the charge leaked to earth. From then the practice has passed through many phases, though customs die hard, as shown by the 1937 report of electrical accidents in factories and workshops, which states that "another instance was found where the end of the earthed wire was put into a bucket of water, the bucket being specially purchased for the purpose and usually placed on a piece of wood 'to avoid leakage' ".

At the other extreme, and typifying the very latest practice, may be cited the proposal to install eight 32 ft. × ½ in. diameter copper rods at a Central Electricity Board substation to secure a resistance of less than one ohm, in soil having a resistivity near the surface of 15,000 ohm-cm. Before 1914 such a resistance would not have been obtained in such soil; in more recent times it might have been obtained, but at a cost at least several times greater than is required to-day; it is now a relatively simple matter. Earthing practice is a good example of the well-known fact that until a quantity can be measured and expressed numerically knowledge is restricted and improvement is slow. For this reason great credit is due to those firms which have produced simple forms of earth-testers which can be used as readily as an insulation-tester. By their use engineers have realized in some measure the limitations of methods of earthing which had been used for many years, they have realized the important effect of the resistivity of the soil, and finally they have found by a few tests that some methods of earthing are far more economical than others.

American engineers profited by a comprehensive publication on earthing issued by the Bureau of Standards in 1918. The recommendations of this report, which are still quoted, were well in advance of British practice at the time, though much has been done to make up the leeway during the last few years. Driven electrodes are now being widely used, and in two important fields, namely, voltage gradients on the ground surface around electrodes and current loading capacity of electrodes, the principal progress has been made in Britain. Research by the Electrical Research Association (E.R.A.) has also shown how the earth resistance of overhead-line towers may be measured without disconnecting the earth wire—a problem in measurement the solution of which is actually of greater importance in other countries than in Great Britain.

All the information necessary to design electrodes economically on a resistance basis is now available and is being used to an appreciable extent. All the research work also that is necessary that has been done on the problem of voltage gradient is available, though it is not as widely known as it should be. The loading capacity problem is still under examination; sufficient information is available to provide a lead in all soils and to give a good guide in clay; when this problem has been completely solved, it will be possible to design electrodes for any condition with as much precision as that of the electric appliances which they protect.

For several years past the E.R.A. has been carrying out investigations into the fundamental problems connected with earthing, and a number of reports have been published. It is considered that the present time is an appropriate one to review the work that has been done, with particular reference to the practical problems of supply undertakings. All the four authors have been closely associated with the E.R.A. researches; most of the work is now published for the first time.

It must be strongly emphasized that the value of the earth has an important bearing on the operation of high-voltage fuses and the protective gear installed. Earth leakage protection installed at the main points of an overhead ring main will ensure the safe operation of the switches by a high-resistance fault. If when the conductor falls the line is not cleared, such a fault may result in a serious accident.

Resistance earthing and so-called 'solid earthing' are general in Great Britain. Reactance earthing of the type practised in America is practically unknown, but tuned resistances (for example, Petersen coils) are now being installed to an appreciable extent. These coils are short-circuited occasionally, and consequently the earth resistance must be such as is required on an ordinary earth system.

In rural areas where the villages are far apart, and where each village is as a rule fed from one substation, the question of low-voltage neutral interconnexion does not occur, and it is here that the difficulty of earthing arises. On urban low-voltage systems it is generally easy to secure low resistances to earth, but in rural areas where water mains are frequently not available for earthing, there are serious difficulties. If it is proposed to work according to the regulations with just one earth, it is necessary to have the substation earth resistance very low (something less than five ohms), and this is frequently very difficult to secure.

In practically all instances in Great Britain where overhead lines have latticed steel towers for supports, these lines carry a continuous earth wire, the function of this wire being to ensure that all extraneous metal work is at earth potential, to act as a release for fault current, and as a protection against lightning. It has now been generally accepted that to make a line secure against lightning it is essential that the continuous earthed wire should be earthed at each tower and that this resistance should be less than about ten ohms. The foundations alone of these towers sometimes have a sufficiently low resistance for other protective purposes.

The earth resistance at consumers' premises should be sufficiently low to blow the largest fuses, but from the economical point of view this is not always possible. This has led undertakings to consider protective multiple earthing, neutralizing or earth-leakage circuit-breakers. The ordinary 18-in. square earth plate or the 3-ft. earth rod is of very little use in the majority of soils found in rural England. Ordinary earthing—that is, one system earth at the substation and the consumer's earth utilizing the public water mains or the cable sheaths—has proved quite satisfactory in urban areas and has been the general practice in Great Britain. The main difficulty with ordinary earthing occurs when the system is overhead and is situated in a district without a piped water supply. The use of strip electrodes has been the means of reducing substation earth resistances to a reasonable figure and deeply driven rod electrodes have also proved useful.

The chief disadvantage of protective multiple earthing is the danger arising from a broken neutral conductor. To minimize the risk the earth resistance of the neutral is made as low as possible, and earths are provided at all consumers' premises. Where the soil resistivity is high (as would generally be the case) this represents a serious expense. The money might be more advantageously expended in ensuring that in the event of only a neutral breaking it would make contact with a live wire and so blow the fuse and disconnect the supply from the faulty section.

In order to determine the reduction of resistance effected by salting, and the frequency with which it is necessary to re-salt electrodes, tests have been in progress over a period of five years in five different sites where various extremes of soil conditions and rainfall exist. Tables are given showing the seasonal change of resistance of electrolytes and the effect of salt and coke treatment. Whilst salting reduces the resistance of earth electrodes it is generally recognized that it increases the rate of corrosion. The following conclusions are of practical importance. Failure of all electrodes in clay soil is caused by the attainment of a temperature of 100° C. at the electrode surface. At this temperature the moisture present evaporates, and the resistivity of the soil increases to a very high value. In clay soil with alternating currents, small leakage currents flowing for a long time do not impair the characteristics of an electrode, since they reduce its resistance. On the other hand, they seriously impair an electrode's characteristics if the electrode is connected to a positive lead. New work is now planned on the behaviour of different types of soil, the requirements of Petersen coil earth electrodes, and the behaviour of long electrodes and electrodes in parallel.

FIRE FIGHTING EQUIPMENT FOR ELECTRICAL INSTALLATION

LAST year the Electricity Commission requested the Electrical Research Association (E.R.A.) to consider what steps should be taken to try to prevent a repetition of one or two disastrous fires that had taken place in connexion with electric power stations and electrical installation. The E.R.A. appointed a committee to consider the whole matter and its report was discussed at the Institution of Electrical Engineers in London on January 25.

Mr. H. W. Swann, H.M. senior electrical inspector for the Home Office, presented the report and opened the discussion. Mr. Swann pointed out that when his committee first took the matter in hand there was a dearth of information available as to the performance of certain media used for fighting fires, and, hearing that a good deal of work had been done in Paris on this subject, the committee paid a visit there and obtained a great deal of information. But it was felt that something more should be done in Great Britain. Luckily, the co-operation was obtained of the County of London Electric Supply Co. at its power station at Barking, and also the help of the London Fire Brigade and the manufacturers of various proprietary media for dealing with fires.

Mr. McMahon introduced the report of the Committee and showed some colour films illustrating in a striking manner the starting and progress of the experimental fires and how they were extinguished. The length of the films taken amounted to 1¾ miles, about ten per cent of which were shown. The films were very instructive and many lessons were obtained from them. All the fires were artificially created and tests were carried out with methyl bromide gas, carbon dioxide, mechanical foam, chemical foam and water, as extinguishing media.

The recommendation made by the E.R.A. Fire Committee is that, for outdoor oil risks, the most suitable form of fixed installation is the atomized water type, or, if local conditions prevent this, then foam should be used. Failing either of them, inert gas media should be used, although when other media are available gas is not recommended. For indoor oil risks, it is stated that where weatherproof metal-clad gear is installed, atomized water will provide adequate protection, subject to precautions being taken to ensure that any apparatus not of the weatherproof type is not liable to suffer serious water damage. Where there are no draughts, gas protection can be applied, and although protection can be obtained with foam, there is the disadvantage that it leaves deposits which may hinder repair operations. For cables in enclosed spaces not liable to draughts, inert gas protection is effective under conditions of rapid operation. Difficulties may be encountered with water and foam. Much the same remarks are applied to cable galleries exposed to the atmosphere, and where gas is not safely applicable then water or foam installations will afford adequate protection. Certain recommendations are also made with regard to portable apparatus, and it is also recommended that back-up protection by means of water hydrants should be provided in case of emergency.

Mr. Nimmo, one of the Electricity Commissioners, remarked that whilst an examination of the films showed that the risk from oil is obviously so great that some might think that the use of oil-less switchgear should be enforced, yet it has to be remembered that there is a great deal of oil gear in everyday use, and steps have to be taken to protect it. In his opinion, water properly applied is the best medium; with the other media used in these tests, experts had applied them. The ordinary user is still left wondering which is the best to use. Usually it was applied by the station personnel. The cooling effect of water gives it a tremendous advantage over carbon dioxide, methyl bromide or carbon tetrachloride. Accepting this, he suggested that for outdoor and indoor transformers and oil and bitumen-filled switchgear, an automatic atomized water installation might be used, and for cable basements and cellars where oil is not likely to be present, ordinary sprinklers would suffice. Finally, he prefers a water pressure of 60 lb. per sq. in. and a ten minutes storage supply to the 50 lb. and four or five minutes recommended in the report.

Mr. C. M. Kerr, who is an officer of the London Fire Brigade and was also a member of the Fire Committee concerned with these tests, spoke of the difficulty of laying down hard-and-fast rules for dealing with these fires and emphasized the need of ample back-up protection; to this, he thinks, too little attention has been given in the report. He also mentioned the need for attention being given to the maintenance of the various forms of fire fighting equipment as a consideration in determining their choice.

Mr. H. Bright said that although the title of the report was "Fire Fighting Equipment for Electrical Installations", it dealt, as did the discussion, solely with power stations. There are, however, installations, such as those in places of entertainment and elsewhere, where the risk of life from oil fires is very much greater than in power stations. In such cases, certain of the media mentioned must be ruled out because of their toxic or suffocating effects. In such places, too, it would be impossible to drain the oil from the transformers into pits, as was suggested for power stations. The alternative seemed to be to have a large tank.

Mr. Hacking, who replied to the discussion, said that the word 'emulsification' was deliberately not used in the report, because satisfactory results had been obtained using water, when there was no question of emulsification. He agreed that the smoke detector should only be used as a detector.

INSECT PESTS OF CROPS IN ENGLAND AND WALES

By Dr. A. D. Imms, F.R.S.

BULLETIN No. 118 of the Ministry of Agriculture and Fisheries, recently issued, records the incidence of the more important crop pests for the years 1935–37. The information upon which it is based has been supplied in the main by the advisory entomologists and other reporters. It appears that numerous foreign insects were intercepted by the Ministry's inspectors during their examination of imported plants and others were sent in by the general public. The great majority of these aliens were unlikely to prove either injurious or to establish themselves in Great Britain. A few, however, were of a different category and need brief reference.

The Colorado beetle (*Leptinotarsa decemlineata*) was represented by a few individuals found in the vicinity of London and Swansea. For the most part they were known to have been introduced through shipping, but no outbreak occurred during the period under review. The chrysanthemum midge (*Diarthronomyia* sp.) first occurred as an outbreak in 1927 but, by 1930, the pest was reported to have been eradicated. After an interval of six years a new infestation was discovered in southern England and appears to have had origin in plants or cuttings imported from the United States. In order to render the position more secure in future the importation of chrysanthemums has now been prohibited, except under special licence, which prescribes rigorous precautions to be observed.

The asparagus fly (*Platyparea pœciloptera*) had not been previously noted in England until it was discovered by C. Warburton in a garden in Hertfordshire in 1935. Subsequent work carried out by the Ministry's inspectors showed that it is too widely established in that county to render any attempt at eradication practicable. The species is a serious asparagus pest on the Continent of Europe and its presence in England may result in the shortening of the productive life of the beds, but it is probable that reasonable commercial control will be attained.

During the period under review, while many of the regular pests of English crops were prevalent, relatively few are specially noteworthy. Mention, however, must be made of the codling moth, which caused very serious damage in most fruit-growing districts during 1935 although it was much less troublesome in the two succeeding years. On the upland pastures of mid-Wales and parts of northern England, outbreaks of larvæ of the antler moth caused loss of sheep-keep. Wheat and oats were seriously attacked by the aphid *Myzus festucæ* in 1935, large acreages in many districts being almost completely ruined. As with the codling moth, the attacks were much less evident in the other two years.

Among unusual records larvæ of the sword grass moths (*Polia vestusta* and *exoleta*) attacking hops and of the holly blue butterfly (*Lycæna argiolus*) injuring raspberries are of interest.

The bulletin also gives a summary of progress as regards insecticides and their application, and concludes with a useful list of references to papers published in Great Britain, during the triennial period, which are concerned with crop pests and related subjects. Viewed as a whole the situation is very satisfactory. Possible danger from the introduction of the apple maggot from Canada and the United States and of the cherry fruit fly from various European countries has been reduced to small proportions by timely action being taken. Also the well-organized watch kept for the Colorado beetle has amply justified itself, since no outbreak has occurred; yet, on the Continent of Europe, its spread eastwards extends yearly and it now has an almost continuous range from southern France to central Germany.

SEVENTY YEARS AGO

NATURE, vol. 1, March 3, 1870

Natural Science at Cambridge

THE Rev. T. G. Bonney, the geologist, concluding an article on this subject, writes: "I may venture to express my conviction, that the coldness and even dislike with which the study of Natural Science was once regarded here is rapidly passing away, that the number of earnest students in the various branches is annually increasing, and that the University is fully alive to the wants of the age; so that, while she can never neglect or forget those old paths of Classics and Mathematics in which many of her sons have won an almost world-wide reputation, she will heartily welcome, and will regard with no less pride, all who are among the followers of sciences of a more recent date."

Measurement of Geological Time

ALFRED RUSSEL WALLACE presents the second and concluding article on this topic. He discusses, in particular, the effects of denudation as shown by Geikie's investigations. Surveying the estimates made by Tylor, Croll, Geikie and Lyell, he deduces a scale of geological time ranging from 24,000,000 years for the beginning of the Cambrian, to 2,000,000 years for the beginning of the Lower Miocene. He continues: "These figures will seem very small to some geologists who have been accustomed to speak of 'millions' as small matters; . . . Taking Sir William Thomson's allowance of a hundred million years for the time during which the earth can have been fit for life, it yet allows Mr. Darwin, for the process of development from the primordial germ, three times as many years anterior to the Cambrian epoch as have elapsed since that date, an amount of time which, I believe, will fully satisfy him, by whatever scale we may measure it."

Industrial Use of an Electric Motor

"FOR many years it has been a query whether the electric current might not be brought so far under man's control as to take the place of steam as a motor for machinery, and success has at last crowned the persevering efforts of scientists. At the last exhibition of the American Institute, there was seen an elliptic lock-stitch sewing machine, driven by a small electric engine which might easily be put into a common hat box. . . . The use of this motor, if it becomes general, cannot fail to prove of the utmost benefit to ladies, especially to machine operators, as it does away entirely with the necessity for using the feet, as is now the case, and must be highly conducive to the health of females, who suffer from many diseases that are generated by the constant strain on the pedal and limb muscles. The inventor of the engine in question is Charles Gaume."

"MR. E. RAY LANKESTER has been elected by examination to the Radcliffe Travelling Fellowship at Oxford."

THE *American Gaslight Journal and Chemical Repertory* states that Professor Loomis, who claims to have discovered a way to transmit messages by electrical air currents without the aid of wires, wants to be appointed Consul to some European port, that he may experiment on the summit of Mont Blanc.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

TWO TEACHERS OF ENGLISH in Timisoara and Iasi—The British Council, 3 Hanover Street, W.1 (quoting 'Rumania') (March 9).

TECHNICAL ASSISTANT in the Mechanical and Electrical Engineer's Section—The Engineer and Manager, Waterworks Department, Town Hall, Manchester 2 (March 16).

ONE SENIOR ASSISTANT and SIX ASSISTANTS for Evening Institutes in Egypt—The British Council, 3 Hanover Street, W.1 (quoting 'Egypt') (March 18).

DIVISIONAL ENGINEER (WIRELESS) for the Malayan Postal Service—The Crown Agents for the Colonies, 4 Millbank, S.W.1 (quoting M/9134).

ECONOMIC WARFARE AND NATIONAL EFFORT

THE dominant conclusion which emerges from the admirable surveys of the work of the Department of Economic Warfare which Mr. Ronald H. Cross has recently given in the House of Commons and in a broadcast talk is that economic warfare is a field which demands very deliberate application of scientific methods if success is to be achieved. Nothing short of a really militant policy, taking full account of the known facts and undeterred by other considerations than its main purpose—that of making it as difficult and as expensive as possible for Germany to obtain her supplies—can be adequate. The task is from the outset more difficult than it was in 1914–18, for Germany now has access by land to the whole of Europe east of France, as well as to the greater part of Asia. We cannot afford to neglect loopholes which might be stopped by more efficient organization or a more scientific policy.

One of the great merits of Mr. Cross's surveys is that they direct the attention of the public not only to what is being done but also to the expansion of that work which is still required. That expansion will demand the co-operation of the public to an extent which will only be possible as a result of a really scientific policy and effective campaign of education. There are many, indeed, in Great Britain who still imagine that we shall win the War without undue disturbance of ourselves. Such easy optimism should at least be shaken by these addresses of Mr. Cross. The discipline already accepted by Germany is not so much a sign of defeat as a challenge that must be taken up by all the democracies. Victory in the great cause for which they contend can only be assured by sacrifices worthy of so great a goal and in no way inferior to those which have been accepted by the enemy.

The accounts which Mr. Cross has given of action taken and projected, however, still afford grounds for the uneasiness with which the Government's attitude in this important matter is regarded in many influential quarters. The concern which has been expressed by Sir William Beveridge and others that the War Cabinet contains no member designated as Minister of Economic Co-ordination or indeed who would appear well fitted for that part, was not dispelled by Lord Stamp's appointment as adviser to a Cabinet Committee on Economic Co-ordination. Recent events, such as the lack of foresight betrayed in a recent debate in the House of Commons on the home production of foodstuffs, have indeed increased it.

Conceived even within the sphere of the Ministry of Economic Warfare, economic warfare is essentially a scientific problem, with all the difficulties involved in conducting operations which bear no relation to normal sound business. So long ago as November an able article contributed to *The Times* argued for an organization on a geographical basis with an economic commander-in-chief, assisted by a small expert economic general staff, corresponding with the organization at the disposal of a military commander-in-chief. Much more is the immense dislocation involved in our transition from a peace-time to a war-time economy a scientific problem which is still incompletely solved. The persistence six months after the outbreak of war of the tragic waste of employment on the scale of a million and a quarter testifies to the absence of organization to utilize the abundant resources which we possess.

These are among the main considerations which have led to renewed representations for reconstruction of the Cabinet, and administrative machinery on lines which would enable all the activities on the economic front to be co-ordinated as parts of one coherent policy for the vigorous and effective prosecution of the War. Among other speakers, Lord Swinton urged that the Cabinet should include a Minister standing in the same relation to the economic department that the Minister for the Co-ordination of Defence does to Service departments. It is true that Lord Stamp is building up a central staff; he has been assisted from the start by Mr. Henry Clay and Mr. H. D. Henderson. Prof. J. Jewkes has now been summoned from Manchester and Mr. E. A. E. Robinson from Cambridge, and it would be unjust to infer that Lord Stamp and his staff are offering no advice on prices, wages, labour mobilization, exports or finance, because the Government has no apparent policy on these matters.

It would appear to be probable that everything that machinery for interdepartmental coordination can achieve is already being done through the committee of permanent heads of departments of which Lord Stamp is chairman, or the Economic Policy Committee of the Cabinet, with Sir John Simon in the chair and Lord Stamp in attendance. What is wanted is central and purposive direction applied not only to interdepartmental matters but also to those that are, formally at least, the concern of one department. Only a Cabinet Minister of Economic Co-ordination can be expected to possess the authority and decision necessary to overcome the obstacles presented by the *laissez-faire* attitude of the Board of Trade in regard to exports or location of industry, the negative views of the Ministry of Labour on its own functions or the inadequate conception of the Ministry of Supply, with its autonomous and secretive controls. The advisability of giving careful consideration to the reconstruction of the Cabinet on the lines recommended by the Machinery of Government Committee of 1918 is more and more apparent as the struggle proceeds.

The administrative problem may be one of scientific management, of bringing into the executive and administrative machinery of government the principles which have been elaborated and tested in large-scale industrial and business organizations and indeed in the Services themselves. The extent to which the whole economic effort of the nation is a problem demanding close scientific analysis is indicated further in an admirable survey of civil needs issued as a broadsheet by P E P (Political and Economic Planning) almost simultaneously with the recent debates on economic warfare in the Houses of Parliament. It reminds us, as did the statements of the Minister of Economic Warfare, of the inexorable demands which war makes on us and the inevitableness of personal sacrifice. It also indicates the chaos and danger which may well result if no guidance is given as to cutting down of unnecessary consumption, and no attempt made to define essential civil needs on a rational basis in relation to the elimination of waste, the conservation of our resources and the most effective implementing of our war effort.

In regard to food, for example, that primary and most essential need, if we are to minimize our large imports of foodstuffs without detriment to standards of nourishment, we must make the best use of the food we consume, by utilizing to the full the discoveries of nutritional science during the last twenty years. Moreover, besides the problem of putting everyone in the position to buy the necessary minimum of foodstuffs, there is the further problem of ensuring that those who can afford enough food are not malnourished through ignorance or physical reasons. Where people are already malnourished to the detriment of their efficiency as workers, an unplanned cut in food consumption would undoubtedly increase this malnutrition and inefficiency. At the same time, a proper use of our knowledge of nutrition might enable us to reduce our gross consumption of foodstuffs without any loss, and perhaps even with an increase, of health and efficiency.

The imposition of rationing without such positive action clearly holds dangers. Both eating and cooking habits may require drastic changes if we are to make the best use of our existing supply of foodstuffs and of the reduced supply which war will inevitably entail. There must be an end to the unbalanced or prejudiced pushing of particular food commodities in the private interests of the seller.

The economic use of the national food supply is largely a scientific question, but it will require firm direction; and national interests must override all other considerations in determining the distribution of such commodities as, for example, barley, between the farmer or smallholder and the brewer. It will be remembered that in 1916 the Royal Society Food (War) Committee, recommending that feeding-stuffs should be fed only to good 'converters' such as dairy cows, calves and pigs, and the production of cheese instead of butter, recommended also the partial or total prohibition of brewing. Moreover, the dependence of British agriculture itself upon imported feeding stuffs raises other problems in relation to the reduction of imports, from the point of view of saving tonnage or of exchange.

Generally, it requires more shipping tonnage to import food for animals than to import food directly for men and women. A shift in agriculture to good 'producers' as recommended by the Royal Society Food Committee would involve a considerable reorganization of British agriculture. Land formerly used for growing fodder is being turned over to growing food for human consumption. The most effective use of the maximum average which must be the objective of British policy can only be secured by making the fullest use of the scientific knowledge available. Such a utilization, coupled with an effective education campaign, leading us to eat differently, involving sacrifice of some imported foodstuffs, and a measure of reorganization in agriculture, should make it possible to reduce our expenditure on food with real advantage to our war effort.

The housing situation also requires scientific analysis and treatment. If it is probable that the civil need for housing can be satisfied during the War at very little cost, the impact of a large reduction in net expenditure on housing not only on the building industry but also on the public works contracting industry, the furniture-making industry and numerous auxiliary industries requires consideration. The appropriate utilization of displaced workers from these industries is a major problem of social planning which has yet to be tackled. After the War, and during it, if there be large-scale air raids, the building industry will occupy a key position. Careless disposal of the key personnel such as architects, quantity surveyors and skilled workers might have serious consequences.

Similarly, national expenditure on transport demands close and scientific study. The possibilities in the elimination of excessive expenditure on daily journeys, with all the advantages that might accrue in the saving of health and time as well as transport, have yet to be examined. Staggering of hours and holidays may become inevitable as available transport facilities are restricted, and economies in expenditure on private transport should in turn reduce the annual deterioration on the roads. Moreover, the development of alternative sources of power in place of petrol for transport is a further and essentially technical problem.

In many other spheres such as clothing, the use of fuel and water supplies, much could be done to eliminate waste by suitable publicity campaigns. The prevention of atmospheric pollution by more efficient means of utilizing coal in domestic houses and the prevention of riparian pollution are two examples in which the co-operation of scientific workers is important. They could also play their part in directing attention to the preventable waste which occurs through ill-health, the ravages of rabbits, rats, weeds, insect pests or animal pests, through neglect to employ scientific methods of control.

There can be no question as to the seriousness of the economic situation. Direct economic warfare is only one of its facets; equally intense drives are required elsewhere to ensure concerted and intelligent thinking, the elaboration of plans based on adequate scientific knowledge and their translation into immediate and appropriate action. The absence of signs of an adequate plan, of organized thinking and resolute action are disquieting aspects of the situation at the present moment.

We cannot escape, as war proceeds, inroads into our standard of living, and so far the Government has lagged far behind that of France in putting before the people the need for sacrifice. Something more than vague generalities is now required. Should it be decided to adopt the plan of a basic 'iron ration' advocated by Prof. J. R. Hicks, fixing rations of a basic list of necessary commodities, corresponding with basic human needs, at guaranteed prices which would ensure that the whole ration would never cost more than a stated sum within the reach of all, the Government can only win the support of a free people by giving evidence of the most rigorous and impartial examination of the situation, and of its own capacity to take the resolute action demanded. We may well have cause to be grateful if the recent utterances of the Minister for Economic Warfare herald a much closer attention to the economic aspects of the War and a scientific examination of the situation which may give concrete guidance to the call for economy and sacrifice.

COLONIAL DEVELOPMENT AND RESEARCH

WHEN on February 20 the House of Commons turned for a brief space from its preoccupation with the War to listen to Mr. Malcolm MacDonald, H.M. Secretary of State for the Colonies, as he announced the decision of the Government in the matter of the report of the West India Royal Commission, 1938–39, it must have been a source of both pride and gratification to the members that, at a time when every resource is strained in the effort to preserve all for which our society and system of government stand, the loyalty and support which the mother country has received from her colonial dependencies should be met by a no less striking manifestation of solicitude on the part of Great Britain for their inhabitants. As already pointed out (see NATURE, March 2, p. 342), the statement of future policy in relation to the development and welfare of the colonies then made by Mr. MacDonald* not only marks a new departure in the relations, financial and other, of the central and local administrations, but it also extends vastly the field in which the sense of responsibility of the mother country for the well-being of the inhabitants of these territories will be enabled to find effective expression. This inter-relation is well defined in the words of the statement itself, that His Majesty's Government, regarding themselves as "trustees for the well-being of the peoples of the Colonial Empire", look upon "the spontaneous and wholehearted support given by the inhabitants of every territory to the common war effort as the best testimony to their appreciation of the way in which that trust is being discharged" ; while on the other hand, it is said, "the primary aim of Colonial policy is to protect and advance the interests of the inhabitants of the Colonies (in which term are included . . . Protectorates and Mandated Territories)".

Mr. MacDonald's announcement is the outcome of no hasty and improvised decision. Indeed, it is stated that this further development of Colonial policy was settled in principle some time ago, and final decisions were postponed only pending the result of the West India inquiry. It has been evident for a considerable period that circumstances, aggravated by the economic depression, not only militated against the social and economic well-being of the inhabitants of, for example, the African dependencies under the Colonial Office, but also were rapidly approaching a stage at which drastic remedial measures, beyond the resources of the local administration, would have to be applied. It is now pointed out that while much has already been accomplished, there is room for further active development of the natural resources of the various territories so as to provide their peoples with improved standards of life.

The conclusion at which the Government has arrived, after consideration of the effect of such limited resources derived from agriculture as are available in most of the dependencies, in relation to a policy of steady development, is that many colonies cannot finance out of their own resources the research and survey work, the schemes of major capital enterprise, and the expansion of administrative and technical staffs, which are necessary for their full and vigorous development. The old principle that a colony should have only those services which it can afford to maintain out of its own resources is to go by the board, and in future, assistance will be given not merely for capital expenditure or material development—in the main the objects of the Colonial Development Fund instituted in 1929—but also the money from new sources now to be provided is to be made available for the maintenance of important works or services over a substantial period of years.

For the sake of clearness, it may not be out of place here to recapitulate briefly the financial arrangements now proposed, and the machinery to be instituted for their employment.

The Colonial Development Fund, instituted in 1929 and limited to a maximum of £1,000,000 a year, will be replaced by a new vote in the estimates for assistance to Colonial Governments up to a maximum of £5,000,000 a year for ten years. This assistance will be available not only for schemes involving capital expenditure for colonial development, but also for helping to meet recurrent expenditure on certain services, such as agriculture, education, health and housing.

Bearing in mind the proposals for research made by Lord Hailey in his "African Survey", the Government proposes to make special provision for research. Hitherto, expenditure on various forms of Colonial research has received assistance from the Colonial Development Fund. In future, for this purpose a separate sum will be allocated up to a maximum amount of £500,000 a year.

---

* Statement of Policy on Colonial Development and Welfare. (Cmd. 6175.) Pp. 8. (London: H.M. Stationery Office, 1940.) 2*d*. net.

As regards the manner of allocating expenditure from these funds, the Government will enlist the help of a Colonial Development and Welfare Advisory Committee, which will be composed partly of official and partly of unofficial members.

In the province of research, in the past the authorities have had recourse in dealing with questions of Colonial research to the advice of scientific and technical experts in Great Britain; but they are now anxious to place the system on a wider and more regular basis. It is considered that this object can be best achieved by the establishment of a Colonial Research Advisory Committee. It is not anticipated that the full scale of expenditure will be reached all at once, especially in present conditions; but so far as possible, steps will be taken immediately to give these proposals effect.

It will be seen that this extension of policy in colonial development represents a very appreciable step in advance. Its most marked effects should be immediately apparent in the removal of the restrictions which virtually, if not in terms, confined previous grants-in-aid to non-recurrent capital expenditure and material development. In no departments of colonial administration have efforts at amelioration been so cramped as in the provision for health services and education—both of paramount importance in raising the standard of well-being among the native populations. By a prolonged course of education alone can the object of the health services really be fully attained.

It is natural that in this much enlarged policy of colonial development the first emphasis should be laid on the improvement of the economic position of the Colonies. Although in any consideration of the amelioration of colonial conditions it has come to be almost a matter of course to consider how and in what way the native population is affected, the interests of the white settler are not to be overlooked. On his shoulders in most instances rests the main burden of the development of the natural resources of the territory; and anything which contributes to promoting the improvement of economic conditions must be to his advantage as well as a further stage in progress towards self-sufficiency.

At the same time, even in such conditions, as always, the foundation of the social and economic structure is the native population. It is this consideration which weighs the argument when it is urged that whatever delay may be imposed on development by current conditions and the claims of the vigorous prosecution of the War, some part at least, and that the more urgent, of the expenditure on research may be pressed forward as a first and immediate charge. Among subjects of inquiry, a plea must be put forward for intensive study of the forms and constitution of native society. That the claims of this line of investigation should be stressed at this late date may seem a work of supererogation. Yet it is a question whether even yet the essential need of intensive study of native institutions and beliefs, and the implications of its conclusions, have been fully recognized, even though anthropologists have been attached officially to recent survey work, such as the nutritional survey in Rhodesia; indirect rule itself, prior to its application, requires an investigation of the character of native institutions before it is possible to make use of them in the administration of native affairs. Recent investigations in West Africa, for example, suggest that indirect rule, where it is now in being, may sometimes rest on an uncertain foundation, notwithstanding preliminary inquiry, when dealing with so complex a matter as the seat of authority in an African community. The farther and deeper goes research in the social anthropology of African peoples, the more patent becomes the closely woven nexus of social and religious or quasi-religious relations of the community. It is impossible to touch the part without affecting the whole.

The significance of further and intensive research in social anthropology as a priority condition of the application of measures of colonial development affecting the native should be obvious. There is no measure of amelioration, whether it be in health, nutrition, agriculture, land tenure, education, housing, or social reform generally, which does not necessarily impinge upon, and to some extent modify, some sides of native life. What those sides are, how extensive their ramifications, and to what extent they may introduce further and unanticipated changes in mode of life, to the disadvantage of the community, the anthropologist is better able than anyone else to say. Many mistakes, reacting to the disadvantage of the native population, have been made in the past in default of such expert guidance. The delay which must supervene in the full application of the new policy of development at least gives opportunity for their avoidance from this cause in the future.

THE PLACE OF SCIENCE IN BRITISH AGRICULTURE

Agriculture in the Twentieth Century
Essays on Research, Practice and Organization to be presented to Sir Daniel Hall. Pp. x+440. (Oxford: Clarendon Press; London: Oxford University Press, 1939.) 15*s*. net.

BRITISH agriculture has always had its problems, its vicissitudes, its hopes; and although still buffeted by forces political, economic and social, it keeps its head erect, conscious of its unique importance and maintaining an undying faith in the return of better times. One impression gained by reading these excellent essays, written by leading exponents of scientific agriculture, and most fittingly dedicated to its Nestor, Sir Daniel Hall, is that of the great difficulties confronting statesmen and administrators when they have to adjust their outlook and their policies to meet new situations, which, in the absence of any long-term plan, have come upon them unforeseen. Until Sir Daniel Hall was appointed to the Development Commission in 1909, scientific knowledge and foresight seem to have been conspicuously lacking in administrative circles, and even to-day they have to contend with reactionary forces, represented by vested interests, the ignorance of science, and that one and only static thing in an ever-changing world, the ultra-conservative mind.

Of the fifteen essays included in the book, four deal exclusively with the relations of agriculture to the State or public authorities, and the rest to scientific and technical advances, mainly in the last forty years. The essays adequately cover all branches except that of agricultural engineering. Mr. H. E. Dale, formerly principal assistant secretary to the Ministry of Agriculture and Fisheries, has some interesting things to relate about Civil servants, whose traditional silence keeps the outside world uninformed of their functions and powers. He admits that order and strength, and not flexibility and freedom of personal initiative, are their peculiar virtues, and tells us that they are as averse from official intervention in the business of agriculture as are the farmers themselves. The growth of this intervention has arisen from the urgent need of keeping agricultural producers on their feet. The policy of assisting home producers by supporting prices, or by compensating them for price reductions due to world conditions, has been the dominant note of all recent legislation; unfortunately, as several writers point out, it has not been accompanied by any direct legislation, for example, on distribution costs, to help the consumer. Dr. J. A. Venn shows how the annual cost of supporting agriculture has lately run into a sum of the order of £60 million. Prof. H. H. Ashby contributes a dispassionate digest of agricultural legislation since 1910, but shows his teeth when he writes: "Neither the State nor agriculturists have ever defined the chief aims of agricultural policy, and for the greater part of the time both parties are pursuing conflicting and to some extent mutually destructive aims". Prof. J. A. Hanley recounts the rise and progress of agricultural education since its beginning in 1890, ending on a cheerful, if controversial, note that "the attitude of farmers and farm workers towards education and research has changed completely—their confidence has been won".

Less optimistic is Prof. C. S. Orwin in his account of "The Farmer's Business". He states that "the evolution of the industry has stopped short at a point half-way between peasant production and scientific management". He urges strongly the use of simple accountancy methods by farmers, but has to deplore that "the practice of scientific book-keeping, as the only means to correct the policy and the practice of the farmer, is so rare as to be virtually non-existent".

Prof. J. A. Scott Watson writes more cheerfully, acknowledging fully the many advances made by applying science to practice. He admits, however, that there has been no essential advance in the art of tillage, and states that "the recipe for success in breeding [stock] is still an ounce of science to a pound of intuitive judgement and half a stone of luck".

In the essays dealing mainly with scientific and technical developments, some of the authors pursue a rigidly historical sequence, which is apt to make 'heavy' reading, whilst others concentrate on the present position using history as a background. Notable among the latter are Sir John Russell's lucid account of "Soil Science in England", and the valuable essay by Dr. C. Crowther on "Some Problems of Animal Nutrition". Sir George Stapledon's treatise on "Grassland" deserves special attention as coming from the pen of a pioneer, a thinker who has shed his academic blinkers, and—one must add—as a 'feeler', for he confesses: "I am sufficiently unscientific, or possibly sufficiently scientific, to permit feeling to colour my scientific judgements and opinions". Dr. R. N. Salaman has a fascinating tale to tell about the rise and progress of research in plant viruses: and Mr. R. G. Hatton's account of developments in fruit-growing discloses a remarkable story of scientific achievement which is probably unknown to most of those who do not work in his field.

The technical essays, in particular, will be of great value to students of scientific agriculture (and for this reason the book should have been provided with an index), and if they are read by the humanist, they can scarcely fail to convince him that although progress may often originate with the practical craftsman, it is science alone that can evaluate inventions and discoveries, stabilize them, and use them as a basis for further advance. It is probably true to say that in the last forty years—the period covered by the book—science has been responsible for many more advances than has untutored practice. And by science we mean controlled observation, measurement, and sound reasoning, not (with due respect to Sir George Stapledon) "feeling", although it may play its part in stimulating research and in applying the results to human betterment. Regarded as literary efforts all the essays are well-phrased and lucid. The only criticism that can be advanced is that some of them are rather overburdened with facts ; a little more play of the scientific imagination, a few more generalizations and ideas, and a livelier style of writing would have leavened the whole and increased its general appeal. Nevertheless, the book is in every way a notable one, and a worthy tribute to an exceptionally worthy man.

E. H. TRIPP.

ELECTRON DIFFRACTION

Theory and Practice of Electron Diffraction
By Prof. G. P. Thomson and Dr. W. Cochrane. Pp. xii+334+10 plates. (London : Macmillan and Co., Ltd., 1939.) 18*s.* net.

THE chief interest attached to electron diffraction at the time of its discovery was the abundant support it brought to the new and exciting ideas regarding a wave mechanics of material particles which de Broglie, Schrödinger and others were then applying with such marked success to the remodelling and rationalization of the Bohr atom. The discovery that electrons are diffracted by crystals left no doubt concerning the reality of the waves associated with matter, and the gratifying agreement between observed wavelengths and those calculated from de Broglie's formula afforded welcome evidence of the correctness of the wave model of the atom and of wave mechanical conceptions in general. The waves associated with matter had, so to speak, been brought into the open, and made available for direct examination.

It is not surprising that experimenters and theorists flocked 'in all directions', as the Russians have it, to this new field. Electron diffraction, like other recently discovered effects in these days of high-pressure research, enjoyed a period of intensive, not to say feverish, investigation during which the main facts and implications of the phenomenon were quickly laid bare. The technique of producing and recording patterns was rapidly improved, particularly for electrons of high speed. All diffraction effects observed with X-rays were shortly duplicated with electrons, including diffraction by molecular gases. The first rough checks of the de Broglie formula were confirmed by precision measurements. The first attempts were made to polarize electron waves by reflection. The relative intensities of diffraction beams were used to calculate the structure factors of crystals and form factors of atoms, with results in general accord with expectations based on existing theory. The dynamical theory of electron diffraction was developed along lines paralleling those followed in the theory of X-ray diffraction. Further, what now seems of prime importance, G. P. Thomson made the first applications of electron diffraction to the study of corrosion films on metal surfaces.

These developments were greatly facilitated by the huge store of knowledge and experience which had accrued from more than twelve years of intensive study of X-ray diffraction. The investigators of electron diffraction had at hand not only a model and guide for their work, but also an enormous fund of data regarding crystal structure and constants. There was some feeling at the time indeed that this store was rather more enormous than one might wish. All the 'easy shots' in crystal analysis had already fallen to X-rays ; electron diffraction had arrived only in time for the cheering —or so it seemed. It was recognized that electrons were suited to the study of exceedingly thin films and to surface layers—fields from which X-rays, because they are scattered but feebly by atoms, are excluded—and that here much of importance was to be learned. It is doubtful, however, if anyone realized how extensive and rich a field this is ; if anyone realized that in their respective fields, electrons would, in certain respects, be more useful for the analysis of crystals than X-rays.

The flow of energy in the primary electron beam is much greater ordinarily than that in the primary X-ray beams. The exposure times for electrons are consequently shorter (of the order of one second) and patterns are recorded at a greater rate, in spite of the fact that with electrons a vacuum must be broken and re-established at frequent intervals for changing plates and specimens. The wave-lengths of high-speed electrons are much shorter than those of the characteristic X-radiations, and this also is advantageous as it results in a greater content of information in the diffraction pattern per unit solid angle about the primary beam. Electron patterns which show twenty-five or thirty Debye-Scherrer rings are not uncommon, and patterns have been obtained which show as many as forty.

Even in the matter of diffraction phenomena, electrons have produced effects not observed with X-rays. The so-called cross-grating patterns, produced by the copious scattering of the extremely short electron waves, are of this class, as are also the Kikucki line patterns which reveal the diffraction of electrons elastically scattered in random directions within a crystal.

All these matters and much else beside, Thomson and Cochrane have set forth in a scholarly and pleasing manner in this new and welcome book on electron diffraction—the first of its scope in English. About one third of the book is devoted to theory. A chapter on general considerations of wave phenomena is followed by more particular examination of the concept of material waves, of crystal structures and diffraction effects. Ewald's invaluable conception of the reciprocal lattice is explained and employed throughout in the interpretation of patterns. Bethe's dynamical theory of electron diffraction is explored in considerable detail in a later chapter, and in another Darwin's theory of polarization is briefly reviewed.

The greater part of the book is given over to experimental technique and to a critical examination of results so far obtained in investigations of thin films and surface layers of gross specimens. Separate chapters are devoted to oil and grease films on metal surfaces, to oxide layers, and to the still controversial question of the physical nature of surfaces which have been mechanically polished. A chapter on the diffraction of low-speed electrons serves chiefly to reveal how much is yet to be learned in this important field. Elsewhere, also, one is struck not only by how much has been accomplished but also by the vast amount of work still to be done. The book is not free from errors: What book in its first edition is? But such as have been noted are few, obvious and innocuous. The authors are to be congratulated on having produced a timely survey and appraisal of our present stock of knowledge regarding the diffraction of electrons.

C. J. DAVISSON.

DESIGN IN AIRCRAFT

Aircraft Design

Vol. 1: Aerodynamics. Pp. xii + 215 + 8 plates. 13*s.* 6*d.* net. Vol. 2: Aerostructures. Pp. xiii + 308 + 10 plates. 16*s.* net. By C. H. Latimer Needham. (London: Chapman and Hall, Ltd., 1939.)

IT is difficult to assess the value of these two books without understanding to whom they are addressed. The author's treatment of his subject is more applied than academic, making it appear to be a designer's handbook rather than a student's text-book. Even then "he falls between two stools", giving neither enough facts and figures for the one, nor fundamental proofs for the other. Nevertheless the subject matter, so far as it goes, is useful and logically treated, and the volume should find a place in any library of aeronautical literature.

Vol. 1, "Aerodynamics", could have been better named "Aerodynamic Design"; it treats the subject entirely from this point of view. In this respect the author has made some unfortunate choices in his examples. In the remarks upon the properties of aerofoils, R.A.F. 15 is the one chosen. This has long been of nothing more than academic interest to the designer. The chapter dealing with the variation of the properties of an aerofoil with its shape is an excellent concept, and gives the designer exactly the lead that he so often needs, having to produce an aerofoil to fulfil a certain performance. The discussion of the effect of Reynolds' number on drag is dangerously vague, and no mention is made of the fact that the roughness of the surface is a vital factor when using results comparatively. Also the effect of structural form, biplane or monoplane, and plan form on induced drag seems to be none too clear.

The chapters on variable lift devices and air-screws are good, being more of an applied nature, but a fuller reference to B. M. Jones's classical method of drag analysis would have been valuable.

Vol. 2, "Aerostructures", is much more clearly defined in its presentation, and gives the impression that here the author is more at home with his subject. Again his choice of examples might have been more up to date. His figures for the comparison between a biplane and a monoplane are based on practice of several years ago. There is an excellent chapter on weight distribution and its estimation, a subject which has seldom been treated properly or as fully in other published text-books. Load factors are also dealt with fully, another subject none too clearly treated in other books. Mention should have been made of the possibility of these being varied as our knowledge of the principles of aerodynamics is extended.

When the author reaches the really practical aspects of design in chapters such as wing design, under-carriages, and metal construction, he becomes very sketchy in his treatment. It is, of course, impossible to treat such subjects in any other fashion in so small a compass, and it might have been better to have covered a smaller field more thoroughly. For example, a chapter on testing scarcely comes within the province of "Aircraft Design". The subject-matter in these chapters is accurate and useful so far as it goes. One is tempted to hope that the author will find it possible to extend future editions, and give his readers the benefit of the detailed knowledge of this part of the subject that he obviously possesses.

PROGRESS IN BIOCHEMISTRY

Annual Review of Biochemistry
James Murray Luck, Editor ; James H. C. Smith, Associate Editor. Vol. 8. Pp. ix+676. (Stanford University P.O., Calif: Annual Reviews, Inc., 1939.) 5 dollars.

THE editors emphasize the need for critically appraising contributions of major significance rather than attempting a mere catalogue of papers, so that presumably this year's reviews, of which there are twenty-five, have been written from this point of view. Even so, they are mostly so highly specialized as to be too difficult for anyone but the experts.

Under the heading biological oxidations, Mr. Dixon notes the discovery of a new coenzyme-nucleotide and of new catalytic flavoproteins. In point of fact, rapid progress is being made in this group, but it requires a year or two yet before the results can be pulled together and a clear story made out of them.

The enzymes are dealt with in two sections, proteolytic and nonproteolytic. The work is now mainly chemical and slow progress is being made. K. Myrbäck devotes a few pages to the discussion of the various amylases : it is now admitted that they belong to clearly different groups producing from starch either alpha maltose or beta maltose or stable dextrins which vary in nature. It is inferred that the starch molecule cannot be so simple as deduced from the formula of Haworth. What a difficult problem starch presents ! It has perhaps the largest literature of any compound and is one of the commonest of substances.

Karl Freudenberg selects lignin for discussion among polysaccharides and has put forward what seems to him the most logical conception of spruce lignin structure. The fundamental type unit, a skeleton containing nine carbon atoms, is a substituted phenyl propane, and it is considered that lignin is composed of a number of similar units connected through an ether linkage between phenol-hydroxyl and the carbinol group of the side chain. The origin of lignin in the plant can only be conjectured. It may come from pectin, but it is more probably derived directly from hexoses. The relation of lignin to the many phenolic glycosides also requires consideration. X-ray studies are doing so much to advance the knowledge of the structure of compounds of biological interest that it is valuable to have a note on this subject from W. T. Astbury.

Chapters follow on fats, proteins, and sulphur compounds and on several branches of metabolism.

There is more work on hormones than ever, particularly in the steroid group relating to sex and adrenocortical hormones. John Freud and two other Dutch workers contribute a very useful summary in which they cite 550 papers and books. The vitamins are distinguished as water-soluble and fat-soluble. There is an interesting note by C. H. Best and J. H. Ridout of Toronto on choline, which acts in the diet to inhibit the accumulation of neutral fat and cholesterol esters in, and accelerates their disappearance from, the liver.

Reference has only been made to half the reviews ; it must suffice to show how much work is going on and how valuable these reports are. Messrs. Murray Luck and James Smith have once more earned the thanks of their biochemical colleagues.

PROTECTION OF THE RADIATION WORKER*

By Dr. G. W. C. Kaye, O.B.E., F.R.S.
National Physical Laboratory

THE basic ideas of protection for radiation workers by the use of remoteness and absorptive shielding are obvious enough: the remarkable thing is the time it took to secure their observance. Naturally, the X-ray tube as evolved by Röntgen and his contemporaries in 1895 onwards was entirely unprotected, but although the explanation was not clear, the dangers of superficial injuries through indiscriminate exposure to the rays had become evident within a few months of their discovery. There were those who attributed the injuries to personal idiosyncrasy, electrical effects, ultra-violet rays, platinum particles from the X-ray tubes, platinocyanides from the fluorescent screens, etc. Among other things, red silk and thin rubber sheet were actually advocated as preventives! Röntgen himself probably escaped hurt for the reason that he conducted his experiments, which were mainly photographic, with the X-ray tubes inside a metal box.

In 1898, a committee appointed by the Röntgen Society collected evidence, much of it confusing, on the harmful effects of the rays. Presently, the principle of absorptive shielding began to emerge, and a distinction was drawn between the effects of 'hard' and 'soft' X-rays. But developments were slow, and so it happened that for many years, protection for most workers continued to be rudimentary or nearly non-existent and, whether owing to apathy or ignorance, injuries and deaths continued to result. The position was aggravated during the War of 1914–18, for many of the X-ray diagnostic sets on which the British army depended were of relatively primitive design. Such outfits, which wholly employed induction coils and gas tubes, were necessarily of restricted output, and exposures, particularly in screen examinations, were often formidable.

BRITISH RECOMMENDATIONS

A series of casualties to a number of prominent X-ray workers during the next few years definitely aroused public opinion. It had become apparent that in addition to general deterioration of health, the signal effects were of three main types: (*a*) injuries to the superficial tissues (usually of the hands) which, with neglect, might become ulcerated or even cancerous; (*b*) prejudicial changes in the blood which might progress to fatal anæmia; and (*c*) derangements of internal organs. More effective protection for the X-ray worker was clearly necessary; but no less important to the X-ray worker was the absolute safeguarding of the patient against accidental over-exposure, particularly in screening and therapy. In 1921 the British X-ray and Radium Protection Committee was formed under the chairmanship of Sir Humphry Rolleston, the members being nominated by various radiological and scientific bodies. It speedily got out a series of protective recommendations which, incidentally, were the first of the kind to be issued by any country, so giving a lead to the world in these matters. These recommendations took cognizance of three primary dangers: (*a*) undue exposure to radiation; (*b*) high-voltage risks from exposed conductors; (*c*) undue exposure to toxic gases produced by coronal discharge. Since 1921, the Committee has revised the recommendations on a number of occasions. In the light of greater knowledge and experience, the recommendations gained in precision and detail, and presently extended their scope to include film storage, electro-medical apparatus and ultra-violet therapy.

The attention of the younger workers may be directed to the difficulties with which the British Committee was confronted in its first efforts to specify and standardize protective measures. The need was great, for the conditions in the majority of X-ray departments were thoroughly unsatisfactory in those days. The Committee realized the pitfalls of a biological unit of dosage, but a bigger obstacle was the absence of an accepted physical unit of quantity of radiation. Only a few workers had attempted to make or utilize physical measurements which could be looked upon as significant or trustworthy; and the best the Committee could do was to try to translate into specific recommendations a sort of grand average of the protective measures which could be gleaned from the working conditions of a number of experienced radiologists who had escaped injury and still enjoyed normal health. A committee which attempts to put forward safety recommendations must err, if it errs at all, on the side of caution, and it was perhaps not surprising that at the first onset the recommendations were regarded by some as unnecessarily drastic, and that the embryonic efforts of the British industry, which backed the Committee's work loyally and wholeheartedly, to provide adequate protection against stray radiation, was deprecated in some quarters as heavy, clumsy and costly, and too cramping for the work of the radiologist. But presently the heavy lead-protected boxes and the like departed in favour of the self-protected X-ray tube in which the full degree of lead protection laid down by the Committee was incorporated in the tube itself, and so made it possible with lighter weight and better mechanical designs to restore the freedom of action to which the radiologist was accustomed.

---

* Substance of the fourth Stanley Melville Memorial Lecture delivered before the Society of Radiographers on February 10.

Looking backward, it is scarcely possible to over-estimate the progressively beneficial influence of the Committee's recommendations on the well-being of the radiation worker, whether in hospitals or industrial and research establishments, as well as on the development and design of X-ray equipment. The Ministry of Health and the Ministry of Pensions gave the recommendations their support, and the National Physical Laboratory collaborated by inspecting some hundreds of hospitals and equipment from the point of view of the recommendations. Furthermore, thanks chiefly to the activities of an Inter-Services Advisory X-ray Committee, which has functioned since 1926, the three British defence services entered the present war with X-ray departments and equipment of which the general standards of safety conform to the Protection Committee's requirements as fully as those of civilian hospitals.

INTERNATIONAL RECOMMENDATIONS

In 1928, at the second International Congress of Radiology at Stockholm, the British Committee submitted proposals based on the British recommendations as a basis for international agreement, the outcome being that they were adopted as international recommendations. An International Protection Commission was also formed with representatives from Great Britain, United States, France, Germany, Italy and Sweden, Dr. Melville and Dr. Kaye being elected secretaries. These recommendations have been revised triennially by the Protection Commission on the occasions of the successive international congresses held in Paris, Zurich and Chicago, and would no doubt have come up again in Berlin this year under happier conditions. Meanwhile, the international recommendations have been adopted in principle throughout virtually the civilized world. They have been implemented by more detailed national recommendations drawn up by protection or safety committees in a number of countries.

X-RAY PROTECTION

From the first, the British recommendations stressed the obvious value to both operator and patient of enveloping an X-ray tube as completely as may be with protective material of a thickness adequate for the X-ray voltage concerned. Such thickness is almost invariably stated in terms of lead, since this is the most effective and convenient absorbent readily available at a reasonable cost. The recommended thicknesses gained in precision as two major steps in progress came about. The first step was the adoption at the Stockholm International Congress of the international röntgen as the unit of quantity of X-radiation, based on an air-ionization method of measurement under specified conditions. The second step was the adoption by the International Protection Commission of a maximum 'tolerance dose' of X-rays. While there are a number of uncertain variables which do not lie within the province of physics but are wholly biological, the erythema dose is commonly accepted on broad grounds as an index of biological response for the average individual, the tolerance dose being taken as 1/1,000 of an erythema dose in three working days, under conditions when the whole body is irradiated. Estimates of the X-ray erythema dose depend on the exciting voltage, but, on the average, evaluate it as equivalent to about 600 röntgens (r.), so that the tolerance dose corresponds to 0·2 röntgen in a normal working day of 7 or 8 hours, or 1 röntgen per working week of 5 days, or 10^{-5} röntgen per second. The protective lead thicknesses for primary X-ray beams which are given up to 600 kv. in the latest International and British recommendations are in general harmony with this tolerance figure under average conditions, corresponding in actual fact to an initial dosage rate of about 2 röntgens per minute at the point to be shielded.

When an X-ray equipment is tested, stray radiation may be evaluated either by a convenient form of dose meter or a Geiger counter, or by carrying on the person a portable ionization chamber of small capacity, or a photographic film. In point of fact, such a film test is very sensitive, blackening which is 'just clearly visible' corresponding (with standard development) to about 0·01–0·02 röntgen (that is, about 1/20–1/10 of the daily tolerance dose), in the case of X-rays of qualities associated with, say, 100–200 kv. The corresponding figure for gamma-rays is about 0·1 röntgen (that is, about one half of the daily tolerance dose).

As regards the protection for X-rays from higher voltages, Mr. W. Binks and I have recently shown, on the basis of theoretical and practical data relating to photo-electric, scattering and nuclear

Exciting voltage (pulsating)	Total lead protection required to give the tolerance dosage rate of 10^{-5} r./sec. at 1 metre distance with 1 milliamp. tube-current (X-rays emitted perpendicular to electron beam)	
	Calculated values (Kaye and Binks)	Experimental measurements (Bouwers and van der Tuuk)
400 kv.	18 mm. lead	17 mm. lead
600	40	36
800	60	57
1000	80	79
2000	175	—
5000	290	—

absorption processes, that it is possible to forecast the appropriate protective lead shielding for any voltage. We have somewhat prophetically extended our calculations up to 5,000 kv., though, in practice, 2,000 kv. is roughly the highest voltage at which X-rays have so far been generated. The validity of the calculations, at any rate up to 1,000 kv., is supported by the good agreement with some experimental results since published by Bouwers and van der Tuuk. This is shown in the accompanying table, where it will be noted that the lead protection required for 1 million-volt X-rays is about 3 inches, for 2 million-volt rays 7 inches, and for 5 million-volt rays nearly a foot.

Incidentally, if we may, not unfairly, regard the X-radiation from a 2-million volt tube as comparable in quality with gamma-rays, then at 1 metre distance from such a tube operating at constant potential, the maximum X-ray output, which is of the order of 210 röntgens per minute, corresponds to the gamma-ray emission at a like distance from 16,000 grams of radium, a figure the magnitude of which may be contrasted with the total of 1,000 grams known to be isolated in the world.

RADIUM PROTECTION

The problems which present themselves in protecting radium workers are more acute and troublesome than with X-rays. A knowledge of the radium contents of radium sources is naturally of service in this connexion. Such measurements were first put on a satisfactory footing when, following the formation at Brussels in 1910 of an International Radium Standards Committee with the late Lord Rutherford as chairman, an International Radium Standard was set up in Paris in 1913, thanks to the skill of the late Mme. Curie and the generosity of the late Sir George Beilby. In the same year, the latter also presented to the National Physical Laboratory the British National Radium Standard, which had been calibrated in terms of the International Standard, and which has since formed the basis of test of nearly 200 grams of radium.

Protection from alpha- and beta-radiations (which are virtually all absorbed in the skin) is fairly readily achieved in the case of most forms of radium manipulation. As regards gamma-radiation, the position is less satisfactory than with X-rays. Progress came when the Fifth International Congress of Radiology in 1937 accepted the röntgen as a unit for measuring gamma-rays as well as X-rays. Furthermore, the International and British Protection Committees were led tentatively to assume, on the evidence available, that the human body is equally susceptible to X-rays and gamma-rays, and adopted the same tolerance dose for both radiations, namely, an average dose over the whole body of 1 röntgen per working week. There is, however, some divergence of opinion on this point, certain workers maintaining that the tolerance dose should be smaller for gamma-rays.

It should be noted that X-ray protective lead values do not apply to gamma-rays, materials lighter than lead being normally more effective against gamma-rays than X-rays. The protective thicknesses for gamma-rays may be estimated sufficiently accurately by assuming that the absorption is proportional to the density. Thus, the introduction of tungsten alloys, with a density half as much again as that of lead, has resulted in smaller and more compact radium 'bombs' without sacrifice of protection. Incidentally, the 'safe working distances' for radium bombs, calculated from the tolerance dose, are less than is often imagined; for example, the safe distance for 1 gram of completely unprotected radium is no more than 5 yards, which is reduced to 1 yard or so by enclosure in a lead bomb with 5 cm. walls. By the same token, there is no necessity, apart from questions of air raids, to locate properly designed and protected radium safes at extravagantly large distances from the personnel.

ELECTRICAL PRECAUTIONS

The practice in the pioneer days of Geissler discharge tubes, of using thin copper wire, unprotected except by silk or cotton covering, to connect the high-tension poles of induction coils or electrical machines to the terminals of discharge tubes, was a legacy which persisted with gas X-ray tubes for many years, for although an unexpected electric shock for the personnel was definitely unpleasant, nothing more serious was likely to follow. Many will recall the slack or dangling high-tension leads which carried, usually in the dark, currents at many thousands of volts, sometimes only a matter of inches from the patient or attendant. Heavier high-tension leads followed in due course, but with the advent of larger coils, and particularly of high-tension transformers, with or without condensers, the power developed was such that greater caution was necessary, and, indeed, fatal accidents began to occur.

The present-day solutions for shock-proofing X-ray outfits take two major forms. One is the shock-proof X-ray tube combined with high-tension cable which, provided with heavy rubber insulation and earthed metallic sheathing, is both shock-proof and sufficiently flexible not to restrict mobility unduly. The other is the complete enclosing of X-ray tube and high-tension transformer in a common earthed metal container filled with a dielectric such as transformer oil or, more recently, 'freon'.

VENTILATION AND LIGHTING

Nowadays there are no two opinions about the Protection Committee's advocacy of light schemes of decoration for all rooms (including photographic dark rooms), together with large windows affording good natural lighting and admitting sunshine and fresh air whenever the rooms are not in use. A bigger step was the introduction of artificial ventilation into X-ray departments. The importance to the operator of generous ventilation is now recognized as second only to that of protection, particularly where apparatus is not corona-free, or the control room is not completely isolated from the treatment room. In some countries, notably the United States, elaborate schemes of air-conditioning are employed.

Mention should here be made of the importance of directional ventilation in preventing the inhaling of radioactive dust or radon during the prolonged manipulation of unsealed radium salt, radium ore, etc. ; cases of radium poisoning have occurred for lack of such precautions.

Finally, this is perhaps the most convenient place to make passing reference to the manner in which the problem of fires associated with film storage was solved by the introduction of non-inflammable cellulose acetate film, in place of the highly inflammable nitrate film.

NEUTRON PROTECTION

The problem of protection for the worker with neutrons seems likely to have a wider interest before long, in view of the invention of the cyclotron by Lawrence and the immense yield of neutrons which can be so obtained. It would appear from recent researches that neutrons can be measured directly in röntgens with reasonable accuracy, and that the biological activity of neutrons may be up to eighty times that of X- or gamma-rays, being probably dependent on the cell structure. In the interests of safety, therefore, it seems well to assume at present that the tolerance dosage rate for neutrons is of the order of 1/100 of that for X- and gamma-rays, that is, about 10^{-7} r./sec.

As regards the protection of personnel against neutrons, the task would be the easier if human tissue were not so effective in absorbing neutrons. Whereas in the case of X- and gamma-rays, the light elements present in tissue are only slightly absorptive, these same elements (or at any rate, the hydrogen) have properties the very reverse where neutrons are concerned. On the other hand, hydrogen-bearing materials such as water or paraffin, if placed around a neutron source, can be turned to account in slowing down and partially absorbing the neutrons before they reach the personnel. In practice, tanks of water or paraffin 50–100 cm. across are used for screening purposes. About 50 cm. of paraffin reduces the total number of neutrons to about 1 per cent, while a few per cent of boric acid in water reduces the slow neutron activity to about one third of that produced by water alone. Having by such means achieved as much absorption of the neutrons as is practicable, further reliance is then placed, as with X- and gamma-rays, on remoteness of the personnel from the neutron source.

INTERNATIONAL MONUMENT TO X-RAY AND RADIUM MARTYRS

What I have tried to set down in this memorial lecture is largely intended for the younger generation who, equipped as they are, like any modern army, with adequate defensive measures, will, I hope, sometimes spare a thought for those X-ray pioneers who, undaunted by long and sometimes unbearable suffering, which drugs might utterly fail to relieve, and which was perhaps followed by mutilating operations or a cruel death, continued to apply themselves indefatigably to perfect the use of Röntgen's discovery for the benefit of humanity. Their martyrdom prepared the way which rendered the present use of X-rays free from danger.

Such matters have a world appeal, though it was in less troubled days that the German Röntgen Society erected in Hamburg a monument to the X-ray and radium martyrs of all nations. The monument, which was unveiled on April 4, 1936, takes the form of a simple rectangular column of sandstone surmounted by a laurel wreath. The names of radiologists, radiographers, physicists, chemists, laboratory workers and nurses whose deaths were due to work with X-rays and radium are engraved on the sides. The total is 169 names spread over fifteen different nations : though it is probable that the list is now by no means complete, nor does it attempt to take cognizance of the large number of less serious casualties.

FOOD PRODUCTION AND FOOD CONTROL*

By Sir John Boyd Orr, F.R.S.,
Rowett Research Institute, Aberdeen

IN anticipation of the War, the Foods (Defence) Plans Committee, working in co-operation with the trades concerned, prepared an elaborate scheme of food control for Great Britain. Excellent though this scheme is in some respects, it is not sufficient to deal with the situation. It does not take account of the fact that, even before the War began, the diet of the poorest third of the population was not up to the standard we now know to be necessary for health. This is the weakest part of the food front. Our food plans should be directed first and foremost to bring the diet of these people up to the standard. If they have sufficient, we need not worry about the rest of the population.

The present system of rationing and price fixing cannot bring about an equal sharing of the available food. Coupons have been issued for 4 oz. of butter and 4 oz. of bacon per week. Even in peace time, when prices were lower, many families could not afford to purchase these amounts. Consequently, we have people with coupons who cannot purchase the rationed amount because they have not the money, and people with plenty of money to purchase the additional amounts they want, but cannot get them because they have not the additional coupons. This fosters an illicit trade in coupons and food which defeats the object of rationing. If the illicit trade does not develop quickly enough, food remains unsold. As the price rises the amount unsold increases until it becomes necessary to increase the rationed amount, so that those with money can purchase more. It is impossible to have two systems, rationing by price and rationing by amount, operating in the same field without creating anomalies. If rationing is to be efficient and to apply to the whole population, the rationed amount must be within the purchasing power of everybody.

Nor does price fixing necessarily benefit the poor. Maximum prices tend to become the minimum. Some commodities have a wide range of prices. Pooling and price fixing will tend to raise the price of the cheapest qualities, which are those that the poor use. Then again, the poor get a less expensive distributive service than the well-to-do. Prices are likely to be fixed on the higher costs of the more expensive service, and the poor may be forced to pay for a service which they cannot afford and indeed will not get.

It is worth while reconsidering the food policy of Great Britain. We are only at the beginning of what may be a long, grim struggle. The issue will depend as much upon the powers of endurance and the morale of the civilian population as on the efficiency of the fighting forces. Next to having a cause worth fighting for and worth dying for, the most important factor for morale is food. In the War of 1914–18, we sustained serious reverses without any loss of spirit, but there was a grave danger of war-weariness in the food shortage of 1917. Our food policy should be designed to raise to the highest possible level national health and physical fitness, upon which morale and powers of endurance so largely depend. It must, therefore, be based upon nutritional needs.

We should first ascertain the total needs of the population, and then determine how these can best be met, keeping in view the possibilities of increasing home production and the need for using the minimum amount of shipping space and foreign exchange for food imports.

In the first place, we must provide more protective foods to bring consumption among the whole population up to the level among the well-to-do, which is about the level required for health. Then we must provide more energy-yielding foods to meet increased energy expenditure due to the War. Unemployed men and men in sedentary occupations need only about 2,500 calories per day. Many of these will be drawn into industry or the fighting forces. In the former case their needs will increase to between 3,000 and 3,500 calories, and in the latter case to about 4,000 calories. We must make provision for a total increase of probably between 10 and 20 per cent.

We are thus faced with the problem of increasing our total food supplies at a time when we must economize in shipping space and in foreign exchange; and if we plan to have the whole population adequately fed, we have the further problem of adjusting prices to purchasing power at a time when the cost of food is rising.

In normal times, about two thirds of the total food supplies of Great Britain are imported. Including feeding stuffs for animals, this takes nearly 20 million tons of shipping per annum. Home production must be increased to the utmost limit and the increase should consist of essential foods which are costly to import in terms of shipping space or foreign exchange. The potato should come first on the list. It is the most important crop in war. An acre of potatoes yields twice as much food as an acre of wheat, and it is the safest crop to take out of newly ploughed-up pastures. In the War of 1914–18, the yield of potatoes from old pastures averaged 7·1 tons per acre compared with a pre-War average of 6·2 tons on ordinary potato land. The potato is of special nutritive value; it is our main source of vitamin C. In Great Britain the average consumption is only about 9 oz. per head per day, though in some families it is as high as 23 oz. In Belgium the average consumption is 19 oz. and in Germany it is 16 oz. We could, with advantage to national health, increase consumption by at least 50 per cent.

---

* The arguments of the present article are set forth at length, with additional data, in a booklet "Feeding the People in War-Time", to appear shortly (London: Macmillan and Co., Ltd.).

The allotment campaign will lead to an increased consumption of vegetables. It is estimated there are about 3½ million gardens in Great Britain, and the number of allotments is likely to be brought up to nearly 1½ million. Out of a total of between 10 and 12 million households in the country, there will thus be nearly 5 million wholly or partially self-supporting in vegetables. If our canning factories are running to full capacity in the summer and autumn, building up a store of preserved vegetables for winter use, and if the distribution of farm-grown vegetables be better organized to reduce the gulf between what the producer gets and the consumer pays, it should be possible to bring consumption of nearly the whole population up to about 6 oz. per head per day, the level among the well-to-do.

Milk is the most important protective food. There is already sufficient milk in Great Britain to bring consumption among the poor, at present less than a quarter of a pint per head per day, up to nearly two thirds of a pint. There should be no great difficulty in making milk, which is at present surplus to the liquid market, available on a cash and carry basis at a price within the reach of working-class families with children.

Milk, vegetables and potatoes between them contain all the food constituents necessary for health. If everybody has sufficient of these, there need be no malnutrition. If we have the right agricultural policy we can produce sufficient for the needs of the whole population, without reducing the pre-War output of other foods.

With sufficient of these three protective foods, we could, if we were forced by lack of shipping space or foreign exchange, limit imports to the cheap, easily carried, energy-yielding foods. The following table shows the estimated storage space, energy value, and price of some of the main foods we import.

The import policy of Great Britain is, of course, affected by trade and other considerations. Thus, for example, we shall import food from eastern Europe, not so much because we need it as to keep it out of the hands of the enemy. Considering only nutritional needs, however, priority in imports should be given to bread and fat, until we have a reserve which puts us beyond the danger of a shortage. In 1914–18 we tried to get a reserve of thirteen weeks' supply, but could not maintain it at that level. With the uncertainty of the present War, we should have at least a six months' reserve of wheat and fat. Of the other foods, sugar is the cheapest energy supplier in terms both of money and shipping space, and would probably be put next to wheat and fat in the list.

	Approx. shipping space (cu. ft. per ton)	Approx. energy value (1,000 cal. per cu. ft. shipping space)	Cost of 100,000 cal
Sugar ..	45	83	4*s*. 6*d*.
Wheat ..	50	56	5*s*. 6*d*.
Fats & tallow	80	118	8*s*. 6*d*.
Dried fruits ..	50	55	21*s*.
Cheese ..	60	56	39*s*.
Frozen beef ..	95	26	40*s*.
Eggs in shell ..	120	12	75*s*.

If we had sufficient of these energy-yielding foods, together with sufficient milk, vegetables and potatoes, we might be reduced to a spartan diet, but there would never be any need for us to capitulate owing to food shortage. A sufficient amount of the energy-yielding foods could be imported with less than a third of the pre-War shipping space devoted to food and feeding stuffs.

Though these three protective foods and three energy-yielding foods might well form the basis of a national dietary in war-time, it is not suggested that the diet of any part of the population should be reduced to these. Even if shipping space were reduced to a minimum, we would have, in addition to these, all the other foods we can produce at home, and it is exceedingly unlikely that the shipping position will ever be so bad that we cannot continue to import other foods.

The most difficult problem is not the maintaining of supplies to meet nutritional needs; it is, as it was in peace time, one of bringing a sufficient amount of the right kind of food within the purchasing power of working-class families with children. It has already been decided to subsidize food. It might be advisable to confine the subsidies to the absolutely essential foods and to make it sufficient to bring the price of these within the purchasing power of every family.

To provide for the different physiological needs and for different likes and dislikes, it would be necessary to leave a margin of money for the purchase of other foods. Thus, for example, if milk, vegetables and potatoes, bread, fat (butter or margarine) and sugar are chosen as the essential foods to be subsidized, and, if it were found that, say 4*s*. 6*d*. a week was the amount available for food among the poorest 10 per cent of the population, the price of these basic foods should be fixed so that a sufficient amount of them can be bought for, say, 3*s*., leaving 1*s*. 6*d*. for the purchase of other foods, such as beef, mutton, fish, fruit, and tea and other beverages.

With such a policy it is doubtful whether it would be worth while maintaining a costly and elaborate organization for the detailed control of food. The Government is the wholesale purchaser. It can fix wholesale prices at a level estimated to have the retail price within the purchasing power of everybody. If the wholesale prices are known and wholesale distribution equitable, competition between merchants and shopkeepers, who are dependent upon the goodwill of their customers, will probably be sufficient to prevent any profiteering. Indeed, it has never been suggested that there was any gross profiteering amongst shopkeepers. Speculation and profiteering, in so far as it existed at all, was in large wholesale dealing, which is now under Government control.

The policy would provide a flexible system for adjusting the national dietary to what we can afford in money or in shipping space. The few essential foods chosen to be subsidized and to be provided in such abundance as there would be no need for rationing, would be regarded as the rock-bottom diet below which we cannot go with safety. Consumption of the other foods could be controlled by price. If we wish to economize in shipping and foreign exchange, we can limit consumption by increasing the price. On the other hand, if supplies of some other foods were sufficient, they could be added to the list of 'essential' subsidized foods and so brought within the reach of everybody. It is most probable that at the present time some other foods such as cheese and dried fruits could be added to the list. If the Government controls the wholesale trade, which is the bottle neck of our food supply, it can regulate consumption as seems desirable by regulating wholesale prices.

In the same way, home production can be regulated by price. The farmer produces for profit. He increases or decreases his output of different foods according to the price he thinks he will get. The farmer should be given a guaranteed minimum price calculated to call forth the additional food we need. The guaranteed prices of the different foods should be adjusted to each other in such proportion that the foods would be produced in the proportion we want. The control of production by the regulation of the price offered would enable farmers to devote their land to the crops for which they are most suited. This would utilize the land of Great Britain to better advantage and give a greater increase in production than a system of compulsory ploughing-up according to a fixed ratio, without any guidance as to what additional foods should be grown.

THE SEVERE WINTER OF 1939-40

THE frost which began on December 27, 1939, and continued with few intermissions until about February 18, 1940, was the most severe in Great Britain since 1895. December 1939 was cold on the whole, the average temperature of 37·8° F. at Kew being nearly 4° F. below the normal; but apart from a short spell of frost about December 22 it did not approach in severity the latter part of the winter. At the end of the month the minimum at Kew fell to 19° F., but comparatively mild conditions returned during the first week in January. The main period of frost came between January 10 and 24, when the mean temperature at Kew was continuously below freezing except for January 12 and fell to 22° F. on January 20. Some very low minima were recorded in all parts of England and Scotland: – 5° F. in the screen at Dalwhinnie, – 6° F. at Bodiam in south-east England and Ambleside in the north-west, and – 10° F. at Rhayader, all between January 17 and 21. At Greenwich the lowest minimum was 12° F., identical with the lowest minimum there in February 1929 and 5° higher than in February 1895. After a short break the month ended with another cold spell, and the mean temperature at Kew was as low as 31·3° F., compared with a normal of 40·5°. February began cold, but severe weather was not encountered until February 10, when another week of frost began, with very low temperatures about February 14.

There was not a great deal of snow in Britain, except in the north, but an even more disastrous phenomenon, glazed frost, occurred over the South and West of England on January 27–28. All through the Saturday night and most of Sunday, fine rain fell through a layer of air which was just below 32° F. The raindrops were cooled below freezing point, but remained liquid until they struck the ground or exposed objects, when they froze instantly into hard clear ice. Twigs and branches of trees, telephone wires and railway tracks were coated several inches thick; one length of telegraph wire in Gloucestershire carried a cylinder of ice 2·4 in. in diameter, and weighing

130 times as much as the wire alone. Mr. C. J. P. Cave calculated that in Hampshire there was a weight of 85–90 lb. of ice on a single wire between adjacent posts. Under the strain, wires and posts gave way, blocking roads and disorganizing the telephone service. Trees were split or brought down by the weight of ice on their branches, and added to the confusion, while the frozen road and rail surfaces caused an almost complete breakdown of transport. The weather continued very cold, and it was some days before conditions approached normal; there was even a second, though less severe, glazed frost on the morning of February 3.

The difference of eleven years between 1929 and 1940 at once suggests the influence of the sunspot cycle, especially when it is remembered that February 1917 also produced a severe frost, while that of 1895 came 22–23 years earlier. All these occurred about one year after a sunspot maximum. There was, however, no similar frost in 1906 or 1907 and the eleven-year recurrence is completely absent before 1895, so that the succession 1917–1929–1940 must be regarded as most probably a coincidence. D. Brunt, in his study "Periodicities in European Weather" (*Phil. Trans. Roy. Soc., Lond.*, A, 225, 247–302), finds no trace of a periodicity of eleven years in the temperatures of London, Stockholm, Paris or Vienna. The cycle of eleven years is the largest periodic element in the temperature of Edinburgh, and shows a minimum about 1938–39; but the double sunspot cycle of 22–23 years is almost equally prominent and is now near its maximum. For London this 22–23 year cycle is the largest component and is likewise near its maximum. In any event the amplitude of these periodic terms is small in comparison with the departures from normal temperature during a severe winter.

The other well-known cycle, Brückner's of thirty-five years, also fails to appear in Brunt's tables for London and Edinburgh, though he found it at Paris and Berlin. It happens that the interval between the last two great frosts, 1895 and 1929, was thirty-four years, but the Brückner cycle is of no help on this occasion, for the winter of 1904–5 was not particularly cold. Nor was 1840, in spite of the supposed grand cycle of a hundred years. Cycles are useless for forecasting severe winters.

On the other hand, although really severe winters may come at irregular intervals, they do present a considerable regularity in the course of events which constitutes them. The greatest intensity of cold rarely occurs until some time in January and quite frequently not until February, and in Great Britain it tends to come in waves of ten or fifteen days separated by brief intervals of milder weather. In a prolonged severe winter, central Europe is occupied by a persistent stream of very cold air coming from the east and north-east, with a temperature sometimes many degrees below 0° F., but over the Atlantic the normal south-westerly winds still prevail. For most of the time the cold winds succeed in crossing the North Sea or English Channel, though sometimes by devious routes, but now and again they give place to the mild south-westerlies. Even the brief passage over the North Sea warms the cold air appreciably, and temperatures in Britain do not fall so low as those on the Continent. Minimum temperatures are not yet available; but at 7h., temperatures only a degree or two above 0° F. were recorded at Copenhagen on January 17 and at Paris on January 23–25. Farther east much lower figures were recorded, down to − 26° F. at Dorpat on January 17. The whole period from about January 1 until January 25 appears to have been generally cold in Europe.

Another cold wave began about February 9, and on February 12, when Copenhagen recorded − 4° F. at 7h., the Baltic between Denmark and Sweden was firmly frozen and, according to reports in the Press, was crossed on foot for the first time in centuries.

OBITUARIES

Colonel R. E. B. Crompton, C.B., F.R.S.

WE deeply regret to record the death on February 15 at ninety-four years of age of Colonel R. E. B. Crompton. He was one of the greatest pioneers both in mechanical road traction and in electrical engineering.

Rookes Evelyn Bell Crompton was born at Sion Hill, Yorkshire, on May 31, 1845. In 1871, he married Elizabeth Gertrude, daughter of George Clarke of Tanfield House, Ripon, and had two sons and three daughters. He was educated at Harrow and served as a naval cadet in the Crimean War (medal and Sebastopol clasp); in the Rifle Brigade (1864–76); in South Africa, 1900 (despatches, Queen's medal with three clasps, C.B.). He was founder of Crompton and Co.; twice president of the Institution of Electrical Engineers; president of the Institution of Automobile Engineers; founder member of the Royal Automobile Club.

Colonel Crompton had a most varied and interesting life and career, and had numerous friends all over the world. Luckily for us, in 1928 he wrote a volume of "Reminiscences" which he dedicated to his wife; "during almost sixty years my courageous fellow-worker and devoted companion". She died on November 27 last, to the great grief of her husband. They had nearly reached the seventieth anniversary of their wedding day.

The Hon. Sir Arthur Stanley, treasurer of St. Thomas's Hospital, London, in an introduction he wrote to Crompton's "Reminiscences", says: "to write the preface to an autobiography is never a very easy task, but when it is the self-told life story of a man of 83, every minute of which has been made to do the work of two, the task becomes well-nigh impossible". One who remembered Lord Alvanley, the celebrated wit, and could speak of the Great Exhibition in Hyde Park as if it were a thing of yesterday, who was a cadet in the Royal Navy at the age of eleven; who, at that early age, went out and received the Crimean War Medal and Sebastopol clasp before reaching the age of twelve, was undoubtedly making a remarkable beginning to a wonderful career.

Then comes a period which is similar to the ordinary life of a lively English boy. When Crompton returned to England he left the Navy, and towards the end of 1856 was sent to school at Elstree to prepare for Harrow. He left Harrow in 1860 and entered the Rifle Brigade three years later. He went to India in the following year, and after serving for a time with his regiment was seconded for special service as superintendent of the Government Steam Train Department. In 1865, when the summer was exceptionally hot, he caught a particularly noxious form of malaria, which troubled him intermittently for many years. He was sent by his doctors to the Murree Hills to convalesce, and made friends with several great sportsmen.

Shortly after this, Crompton received a staff appointment at the Umballa Durbar, and got into touch with several influential men at headquarters. He was invited by the commander-in-chief to the aides-de-camp quarters at Simla, and he was successful in interesting them in his project of substituting mechanical transport for the bullock trains which at that time were generally employed for army purposes. He was appointed an extra aide-de-camp to the commander-in-chief, and in this capacity was often asked to accompany Lord Mayo, the Viceroy, on his rides. His own road engine (the *Blue Bell*), which he had practically completed before he left for India and which travelled at an average speed of four miles per hour, had been left in the hands of R. W. Thomson of Edinburgh, to develop. Through the good services of the Director-General of the Post Office, who controlled the bullock train service in India, the first *Blue Bell* 6 h.p. road vehicle was ordered and Crompton received the official appointment as "Superintendent of the Government Steam Train", so as to take charge of the experiments. He was temporarily withdrawn from the army in order that this could be done. After many difficulties and adventures with the *Blue Bell* in India, his return to London was of an unusual kind, as the Franco-Prussian War was on and Paris was invested. Eventually the German military authorities gave them permission to proceed, provided they put on uniforms and wore their swords to show that they were officers.

At this time, mechanical road transport in England was limited to the agricultural traction engines, which were allowed, as a favour, to clank along the high roads at the speed of the man who walked in front with a red flag, and even at those low speeds their hauling capacity was very poor. Thomson, by his invention of rubber tyres of great cross-section which flattened themselves under the weight of the engine, at once doubled the hauling power and allowed his engines to be run at speeds up to ten miles an hour whenever the Red Flag Act permitted it.

From 1878 until 1882, Crompton carried on a business as an electrical manufacturer, confining himself to the manufacture of electrical arc plant. The firm sold and installed Gramme generators and Bürgin dynamo machines, for the latter of which it acquired the sole right of manufacture. These machines could supply from six to eight arc lamps in series, and so the firm could undertake the lighting of railway stations, goods yards, docks and other open places in which work has to be carried on at night; and for such purposes the firm found a ready market. An order to light St. Enoch Station, Glasgow, with arc lamps was obtained, and the interest taken in this work by Sir William Thomson (Lord Kelvin) cemented a friendship between them which was helpful to both.

Willans the engine-builder, about this time (1879–1880), was a frequent visitor at Crompton's house in Porchester Gardens. They were both interested in electrical development and were able to discuss together and help one another in their respective difficulties. They agreed that the generator sets of the future must consist of a high-speed engine coupled direct to a direct current dynamo. During 1879, Cromptons designed many portable sets of electric lighting plant. Combined with this set, the first Willans high-speed compound engine gave such remarkably economical results that it attracted great attention from the engineering world. About Christmas, 1879, Crompton lighted up his own house in Porchester Gardens. At first he used primary cells, but they were not a success, so he brought in one of his portable sets into the mews at the back of his house and gave special parties, using small arc lights fixed in his drawing-room and dining-room. This was probably the first instance of effective electric lighting in a private house, although there had previously been exhibitions of arc lighting at the Royal Institution and elsewhere.

Early in the year 1880, a messenger from Messrs. Mawson and Swan, the well-known chemists of Newcastle, to whom Crompton had supplied arc lighting plant, called on him to say that Mr. Swan urgently desired to see him. He went to Newcastle, where Swan took him to his laboratory and showed him twenty small incandescent lamps, which burned very brightly and steadily, each having a carbon filament enclosed in a globe, exhausted to a very perfect vacuum, and claimed that he had solved the problem of electric light for internal illumination. Crompton agreed with him. Later in the same year (1881), the great German physicist Helmholtz lectured at University College, London, and for the illustration of his experimental work Crompton supplied him with one of his portable sets of generating plant. For the International Exposition of Electric Lighting held in Paris in the summer and autumn of 1881 in the Palais de l'Industrie, Cromptons sent over a fine exhibit, and were awarded the first gold medal ever given for electric lighting plant.

The great fire which in 1883 destroyed the Ring Theatre of Vienna with great loss of life so impressed on the Emperor Francis Joseph the dangers of gas that he asked the Imperial and Continental Gas Company, which then supplied gas for the lighting of Vienna, whether it could not arrange for the lighting of the Opera House and the other Imperial theatres by electricity as being a safer and better illuminant. The Gas Company, advised by Prof. Monnier of the École Centrale in Paris, suggested that Crompton should be called in for consultation, and so in June 1885 he went with Prof. Monnier to Vienna and spent some weeks in considering the Emperor's question. At this time a small central station had been started in Berlin in the Friedrichstrasse. In London, the original Edison Company had done the same at a point near the Holborn Viaduct, and the Grosvenor Gallery scheme was in its initial stage. At this time the Swan Company had succeeded in turning out satisfactorily 100-volt lamps. At Vienna the company designed from its central station in the Schenkenstrasse 440-volt generators and laid twin conductors to carry this pressure up to the Opera House. Babcock and Wilcox boilers were some of those used. Part of the Vienna plant was delivered in the spring of 1886, and when more plant was required, Crompton went to Witcowitz in Moravia to give instructions for the boiler work.

The old Emperor Francis Joseph showed great interest in the electrical work when in progress, and very frequently came to watch the workmen, generally accompanied by his son, the Crown Prince. He paid Crompton the high compliment of saying that he wished his son Rudolph to be a good deal with them as a sort of pupil.

As soon as new scenic effects were made possible by electric lighting, Crompton had to spend a good deal of his time on the stage of the Grand Opera. This threw him into the society of Richter, who had already made his name as the great conductor of opera in London and was then endeavouring to reconcile old-time opera with the Wagnerism that was then just commencing. At that time there were two directors of the Grand Opera, Richter, who stood rather for the old school, and Jahn, who was all for Wagner and the Wagner school. They used to have great arguments and ask Crompton for his opinion on musical points. Crompton disclaimed all pretence of being an authority on music, although his mother had known Mendelssohn well at the time of his apogee and was acquainted with very many of the musical world at that time.

In 1896, Dr. John Hopkinson, who had succeeded Colonel Crompton as president of the Institution of Electrical Engineers, discussed the possibility of forming a corps of electrical engineers. This was accepted by the War Office, and Hopkinson took command with the rank of major in the Royal Engineers, Crompton being the senior captain. Four or five men well known in the electrical profession, including Hopkinson's eldest son Bertie, also joined the corps as officers. After training at Alum Bay in the Isle of Wight, Dr. Hopkinson left the corps to join his family in Switzerland. But a few weeks later the sad news arrived that he and two members of his family had been killed when climbing on the Alps, and so the whole work of training and organization of the corps fell on Crompton's shoulders.

Throughout the years which followed his return from the Boer War until 1914, Crompton never ceased from his efforts to persuade the War Office to interest itself in the introduction of mechanical transport, not only for war material, but also for the haulage into position of guns of greater power than had been hitherto used.

In an epilogue to his book of reminiscences Crompton says, quoting from an address he delivered to the borough authorities of Chelmsford in 1900, at the time when that town received its first cheap electrical supply:

"England in future, instead of being spoilt by densely populated industrial centres, might be covered with cottages extending for miles over the present almost uninhabited rural districts, so that the population would be more evenly spread over the kingdom. The factory hands, instead of having to work under the shafting in factories, should be able by the electrical transmission of power to carry on industrial pursuits in their own cottage homes. That is the future which lies before electrical engineers if they have the pluck and energy to force their views upon the public to a sufficient extent. The thing has been done in Switzerland, in Sweden and elsewhere on the Continent, and if I can live to see it accomplished in our own country, I shall be proud to have contributed in some degree to the solution of all the greatest problems of distribution."

ALEXANDER RUSSELL.

Prof. Ludwig Hopf

THE death of Prof. Ludwig Hopf occurred on December 21 at Dublin, only a few months after he had been appointed lecturer in applied mathematics at Trinity College, Dublin. Dr. Hopf went as a refugee to Cambridge in April 1939, after having lost his position as professor of applied mathematics at the Technische Hochschule, Aachen, on racial grounds soon after the Nazis came into power. He had been on the staff of the Hochschule since 1914 and had become one of its most popular teachers.

As one of the first pupils of Sommerfeld at Munich, Hopf graduated in 1909 with a thesis on the problem of turbulent flow in a river. He worked in particular on the influence of the roughness of the walls of a canal on the transition from laminary to turbulent flow. This work brought him into contact with the Mittlere Isar water regulation and drainage scheme, to which he was scientific adviser for several years. During the War of 1914–18, Hopf did valuable work on problems of stability of aeroplanes, and his collaboration with R. Fuchs led to their well-known monograph on aerodynamics. In the second edition (1934) the book was divided into three volumes, Hopf being responsible for the first, which dealt with general principles. This is still being used as the chief text-book for aeroplane designers in Germany.

In the early days of relativity and of quantum theory, Hopf collaborated with Einstein (1910–11). Several papers on radiation dating from that time, and a recent well-written popular account of matter and radiation (Springer, 1936) bear witness to his interest in this subject. More recently, Hopf studied the methods of solving linear differential equations in separate domains with the view of finding the relation between the corresponding solutions. A first paper appeared in 1935, and important applications to physical problems were to follow. The many friends of this genial and kind-hearted mathematician will deeply regret the loss they have suffered.

Prince Ginori-Conti

When Prince Piero Ginori-Conti died on December 9, Italy lost one of her most energetic industrial personalities and international science a devoted supporter. His name will always be associated with the industrial utilization of the volcanic springs in the Lardarello district of Tuscany. Thanks to his 'drive' and business acumen, these waters were made to generate electric current for transmission to Florence and Pisa, and to yield boric acid, carbon dioxide, etc., for industrial use. In the chemical works connected with this great undertaking, he was much helped by Prof. R. Nasini, and on the engineering side his son, Dr. Giovanni, one of the three children by his first wife, was of great assistance. An article on the Lardarello development appeared in NATURE of January 14, 1928, p. 59.

Ginori-Conti was born in 1865 as a scion of two ancient Italian families, Ginori and Conti, and on the latter side he claimed relationship with the Scottish Mackenzies. His title of Prince of Trevignano was inherited; that of Senator was granted him later in life. His first wife was the daughter of the Count of Lardarel, the owner of the springs, and his second wife was a French lady. A charming personality, Prince Ginori-Conti came frequently to London where, as a member of the executive committee of the Union Internationale de la Chimie, and as an honorary member of the Society of Chemical Industry, his visits were much appreciated by numerous friends.

Prof. Alexandru Slatineanu

Prof. Alexandru Slatineanu, a leading Rumanian bacteriologist and hygienist, who died on November 27, 1939, was born at Bucharest on January 5, 1873. He studied medicine in Paris under Berger, Dejerine, Babinski and Metchnikoff, in whose laboratory at the Pasteur Institute he made the acquaintance of his compatriot Prof. Cantacuzène, with whom he was closely associated henceforth. He qualified in 1901 with a thesis on experimental *Bacillus pfeiffer septicœmia*, for which he received the university medal awarded for theses of outstanding merit.

From 1902 until 1912, when he was appointed professor of bacteriology at Jassy, Slatineanu acted as chief assistant to Cantacuzène at Bucharest in his work on experimental medicine and the reorganization of the Rumanian health services. At Jassy he founded an institute of hygiene of which he was made director, and also organized an isolation hospital for infectious diseases. In 1917 he took an active part in the campaign against typhus fever which was then very prevalent in Moldavia. In 1931 he was appointed general secretary of the Rumanian Ministry of Health under Prof. Cantacuzène, who was the minister of that office. He was the author of numerous articles on infectious diseases which were published in French in the *Comptes rendus de la Société de Biologie, Bulletin de la Société de Pathologie Exotique, Archives roumains de Pathologie*, or in Rumanian in the *Revista Stintelor Medicale*.

J. D. Rolleston.

Dr. E. M. Mikkola

Dr. Erkki Mikael Mikkola, geologist of the Geological Commission of Finland, was killed at Taipale on February 13. Mikkola, who was born in 1907, had become a leading authority in Pre-Cambrian geology, possessing an intuitive faculty of seeing through a geological formation, and picturing it correctly in space and time. His scientific studies led him from botany to geography, quaternary geology, tectonics and petrology. His three Lapland maps are given a foremost place among Pre-Cambrian sheets of the Finnish Geological Survey. Their description in English is a monograph of fundamental value.

When the Russian attack developed on November 30, Mikkola, as a lieutenant in the reserve, went to join his company, leaving the Geological Survey at Helsinki just one hour before it was destroyed during a bombing raid. Thereafter he spent all his time, two and a half months, in the front lines, taking a full share in the dangers of the heroic defence.

We regret to announce the following deaths:

Prof. C. D. Marx, emeritus professor of civil engineering in Stanford University, on December 31, aged eighty-two years.

Mr. H. C. Newton, first chairman of Messrs. Newton and Wright, Ltd., London, manufacturers of X-ray equipment, on February 19, aged eighty years.

NEWS AND VIEWS

Lord Halifax and International Affairs

MANY speeches dealing with the present crisis have been made since the War began six months ago. That of Lord Halifax at Oxford on February 27 surpassed them all not only in the clarity with which the fundamental issues at stake were set forth, but also in the eloquent and moving enunciation of their relation to a philosophy of life which looks beyond the individual ideal to an aim worthy of the pursuit of mankind at large. Addressing his audience, as he said, with the dual personality of Chancellor of the University and H.M. Secretary of State for Foreign Affairs, Lord Halifax made no attempt to gloss over the facts, unpleasing as they may be, or to ignore the grave dangers for the future of civilization which they imply. The one fact by which above all he is appalled is that this "waste land" we live in, as the present state of European civilization has been called, has been brought about not by the mistakes, the pride, and the selfishness of an older generation, but by that of youth, deprived of the elements of true judgment, which has been the driving force behind the Nazi movement. But, if on one side force is an instrument of aggression, on the other, youth will fight to break down the barrier which must be broken down, if the youth of Europe is to avoid living always in this "waste land".

The antagonisms which have brought about the present conflict in Europe are by now familiar in terms to all; but as formulated by Lord Halifax before an audience composed largely of those whose task will be to ensure that right prevails, they are seen to penetrate to the very fundamentals of human associations. On one side is an all-embracing and overpowering system—a system based on the conception of the so-called economic man—and over against it the ideal which has made as its end the perfection of the individual "in the conviction that here, too, lay the secret of life for all society". It must be remembered that "the substance of any conventional code . . . must derive from the depreciation by society of the principles of its own survival" and, he went on to say, "If we are to recapture the secret of order for international society . . . we must as individuals strive to erect or maintain standards that will bring true freedom through the way of discipline". If any good thing can come out of so great an evil, it is that the outbreak of War has constrained the British peoples to reason with themselves upon the nature and aims of the societies in which they live. If there still be those in whose minds there lingers a doubt, they cannot fail now to see the issues clearly in the light of what Lord Halifax has said.

Universities in War-time

DR. RAYMOND PRIESTLEY, vice-chancellor of the University of Birmingham, devoted his address at the annual meeting of the Court of Governors of the University to a discussion of war conditions. He said that the university, until now, has fared very well. Numbers are almost up to normal and on the science and applied science side the great majority of students will remain until they have graduated. "Reservation is not intended to prevent, and will not prevent, university-trained youth from playing its part in the country's war effort. Their advent is merely deferred until they are fully prepared to pull their weight." In this way fully trained men will become available at the end of each academic year, and there will be a proportion able to play their part in the reconstruction that must follow the end of the War if European civilization is to make up leeway and resume its advance. Dr. Priestley went on to say that he believed it is not necessarily bad for young university men to pass through the Army, the Navy, or the Air Force on the way to their normal work in the world. He quoted his own experience of the War of 1914–18: "I came out of it a better man—more humane and better able to deal with situations and with men". When the War ends, the universities and university men will have a more important part to play even than in war-time, and it would be fatal if a false impression got abroad that university personnel claims to be set apart from the generality of citizens.

The recognition by the Government that the work of the universities of Great Britain is part of the national cause in the War has provoked criticism. Dr. Priestley believes this to be unfair. Indeed, he thinks that there can never have been an occasion when, in similar circumstances of national strain, a Government has been more far-sighted in this particular respect. In the War of 1914–18, education almost closed down. By the decision to refrain from enlisting the youth of the nation before the age of twenty, the Government has given technical and university education a chance to continue their task. For this purpose the universities require adequate finance. "They provide the technical experts on whom the servicing of the post-War world will depend. They provide the teachers who must tune to concert pitch the bodies and minds of succeeding generations. They ought to produce a large proportion of the enlightened leaders for the new era. Certainly if they do not, leadership, though it may be powerful, will not be enlightened." He also referred to the universities as "the chief repositories, exponents, and defenders of that freedom of thought that has been quenched in the totalitarian State".

Evacuation of Schoolchildren

THE Government Evacuation Scheme is reviewed in a Circular (No. 1965) to county councils and local authorities and an accompanying memorandum (Memo. Ev. 8. (London: H.M. Stationery Office. 4*d.* net)), which explain in detail the scheme recently announced by the President of the Board of Education. More than 400,000 evacuated schoolchildren remain in the reception areas, and the Government is of the opinion that dispersal of children from the evacuating areas is as desirable now as it was at the outbreak of the War. The first objective of policy is therefore to ensure that there is no further drift back of those children to the evacuation areas. To secure an equitable distribution of the burden of private billeting, householders in reception areas are to be invited to place their names on a roll, one of the primary objects of which will be to secure a list of persons willing to share with their neighbours in the care of children who have been billeted since the outbreak of war. Local authorities also have compulsory powers if the voluntary response is insufficient. At the same time, the billeting allowance has been increased to 10*s.* 6*d.* a week for all schoolchildren of fourteen years and over as from March 2.

The further plans to be made for evacuation are for schoolchildren only, and will only be operated if air raids develop on a scale involving serious and continuing perils to civilian population. Evacuation will remain on a voluntary basis, but parents registering their children will be asked to sign undertakings that they will send them with the school party if evacuation is ordered and that they intend to leave them in the reception area until the party returns. The areas to be evacuated will be the same as those evacuated in September 1939, but the decision to evacuate any area will be taken in the light of prevailing conditions. Not less than 36 hours notice will be given to any particular area, and specified parties will be taken as far as possible to specified destinations. Children found to be suffering from infection or disease or serious uncleanliness are not to be billeted on householders in that condition. While the fullest possible use is to be made of the camps provided by the Government, the contribution from this source is limited. To supplement this, each receiving authority is being asked to provide hostels available for about 5 per cent of the children to be received, utilizing for this purpose a certain number of empty houses.

Institute of Chemistry

IN submitting the annual report of the Council at the sixty-second annual general meeting of the Institute of Chemistry, Sir Robert Pickard, senior vice-president, who presided, owing to the death of the president, Mr. W. A. S. Calder, early in January, said that the Institute, as the professional organization of chemists, has assisted the Government in supplying its needs in technical personnel for industries essential in war-time. The roll of the Institute continues to increase and now numbers more than 7,550, more than five times as many members as were registered in 1914. Those who could remember the position forty years ago, and recall the difficulty at that time of making any headway in the profession of chemistry, have watched the astonishing increase in the number of chemists, their growing influence, the increasing applications of science and the steady absorption of chemical talent in industry and commerce, in Government and municipal service, and in the affairs of everyday life. The profession of chemistry now stands high in the public esteem as a very essential service.

The report of the honorary treasurer of the Institute shows that the Institute is financially in a sound condition. Referring to the burden of publication expenses, he expressed the hope that the fund which had been raised by the Chemical Council, from industry as well as from chemists themselves, will help to put the affairs of the publishing societies—the Chemical Society and the Society of Chemical Industry—on a sounder financial basis. The officers and council for the ensuing session were elected, the new president being Dr. J. J. Fox, Government Chemist.

Relics of Ancient Egyptian Royalty

THE black granite sarcophagus of Pharaoh Psusennes, discovered at San el Hagar, the ancient Tanis, by Prof. Montet of the University of Strasbourg (see NATURE, February 24, p. 300), was opened in the presence of King Farouk on February 28. Inside, it is reported (*The Times*, February 29), was a silver sarcophagus, about 7 ft. long, in the likeness of King Psusennes. On the head were the royal insignia, and in the hands, which were folded across the chest, were a sceptre and a flail. The state of preservation and the exquisite carving are said to combine in making this one of the most beautiful objects discovered in recent years. The silver sarcophagus was in two pieces. Inside it was another sarcophagus, of which the top was a silver-gilt body-covering and a gold mask, also a likeness of the king. On the chest are long inscriptions, apparently religious texts. The lower half of the coffin had been of some metal, which had completely disappeared owing to the damp that had seeped in between cracks. In consequence, the mummy also had disappeared, only a mass of mud being left, in which were a few bones.

On the removal of the sarcophagi, a mass of fine jewellery was found in the granite case. Twenty-one gold bracelets, ten from the right arm and eleven from the left arm of Psusennes, all bear inscriptions which trace the king's genealogical tree and give details which will be of importance for the history of a period obscure in its dynastic relationships. Inscriptions giving the names of the king's mother and uncles, pointing to a possible connexion with Thebes, have already been deciphered. Many gold necklaces, some adorned with rubies and scarabs, were found, as well as finger and toe cases of gold. Photographs of the site, sarcophagi, and some of the finds appeared in *The Times* of February 29.

University of Birmingham

AT the annual meeting of the Court of Governors, the Pro-Chancellor, Mr. E. P. Beale, welcomed, with relief, the announcement that the Treasury grant to the universities is not to be reduced. He also announced with gratification that contributions from the Birmingham City Council and the surrounding local authorities showed a substantial increase, due mainly to the grant of an additional £750 from the Warwickshire County Council. He regretted that it had been necessary, owing to lack of financial support, to close the Department of Industrial Hygiene and Medicine; he hoped the setback would be only temporary. He also referred to the endowment of a chair of theology by Dr. Edward Cadbury. The endowment fund (£32,000) is the largest individual benefaction received by the University in 1939.

The Nuffield Physics Laboratory is now occupied. The magnet of the large cyclotron has been erected free of charge by Messrs. Horsley Bridge and Thomas Piggott, Ltd., of Tipton, the steel for its construction having been supplied on most generous terms by Messrs. Colvilles, Ltd., of Glasgow. Prof. S. Zuckerman, who was appointed to the chair of anatomy to succeed Prof. R. D. Lockhart, is engaged on work of national importance and it has been agreed that, in consequence, he shall postpone taking up duty at Birmingham. Dr. C. F. V. Smout is continuing to act as temporary head of the department.

Higher Education in Palestine

THE Friends of the Hebrew University of Jerusalem have just published their annual report, 1938–39 (199 Piccadilly, London). This University is an important centre of culture in a distracted country and continues, we are glad to see, constructive effort, though faced with financial uncertainty. A new Medical Centre was opened last year, including a fine hospital with three hundred beds and first-rate equipment. For the present it will be mainly devoted to medical research and post-graduate courses. Progress has been made with agriculture and education, for which eight diplomas were awarded last year. The University is enterprising enough to broadcast popular talks on its work, and its friends are busy in Great Britain seeking to make up for losses due to the War. It is hoped that some special donations may help a large number of students who, coming from countries under German domination, can no longer receive the money on which they formerly relied. It is estimated that £6,000 will be needed for urgent cases.

The Hebrew Technical Institute, Haifa, has altogether more than seven hundred students and a staff augmented by some distinguished refugees. A Nautical School was started in 1938 and has its own training ship. The Daniel Sieff Research Institute has been experimenting, for the benefit of the orange industry, on peels and other waste products. Difficulties of transport will keep much of the present crop at home. Johnson used orange peel for indigestion, but it is scarcely likely to survive to-day as a remedy.

The Blind Spot

HELMHOLTZ, in his "Handbuch der physiologischen Optik" (1867), stated that the demonstration of the blind spot of the eye, the discovery of which was communicated by the Abbé Edme Mariotte to the Royal Academy of Sciences in France in the winter of 1667–68, was given before the King of England in 1668. Dr. J. Bröns, of Copenhagen, in a monograph on "The Blind Spot of Mariotte" (London: H. K. Lewis and Co., Ltd., 1939. 12*s.* net), proves that this statement is erroneous, and brings forward strong evidence of the manner in which it arose. In 1776, Georg Simon Klügel, professor of mathematics in the University of Helmstädt, published a translation of Joseph Priestley's "The History and present state of Discoveries relating to Vision, Light and Colours" (London, 1772). On p. 144 of the translation there is a footnote as follows: "(a) Smith's Opticks, Remarks, p. 6 (d. d. Ausg. S. 367). Oeuvres de Mariotte, p. 496. (Der Versuch ist 1668 vor dem Könige von England gemacht. Birch, T. 2, p. 281. Haller's Phys., T. 5, p. 470, K.)" The reference to Birch shows that the communication to the Royal Society was made by Oldenburg, and not by Mariotte, and there is good evidence that the king was not present at that, or indeed any other, meeting. The reference to Albrecht von Haller, also a footnote, is in his "Elementa physiolgiæ corporis humani" (Lausanne, 1763), also contained in his "Anfangsgründe der Physiologie", S, p. 470, Berlin-Leipzig, 1772. This reads as follows: "Factum ann. 1668 coram S. Reg. Maj. T. Birch, T.II, p. 281. Exstat oper. Mariot. p. 496, Ed. Holl.". Dr. Bröns thinks that Klügel expanded the footnote to "Factum anno 1668 coram *Sua* Regia Majestate", adding his translation "Der Versuch ist 1668 vor dem Könige von England gemacht", whereas it should read "Factum anno 1668 coram *Societate* Regiæ Majestatis"—"the experiment was shown before the Royal Society".

Progress at the British Museum

IT is strange to read in the recently published annual report of the British Museum of events like the special Thomas Cromwell exhibition and, in the Natural History Museum, the retirement of Dr. Tate Regan and succession of Dr. C. Foster-Cooper, which seem to be matters of ancient history, but perhaps that is inevitable when H.M. Stationery Office issues the Museum's Annual Report for 1938 at the end of 1939. The interest of the public in museums has been undoubtedly on the up-grade in recent years, and this is reflected in an increased attendance (7,720) at the Natural History Museum. It is more difficult to account for the serious fall of more than 80,000 in the number of visitors at the British Museum, where the total, still exceeding one million, was the lowest since 1926. Perhaps the decrease was a reflection of the international disturbances in the autumn of 1938, for the work involved in air raid precautions, in training the staff in anti-gas measures, and planning for the safety of the invaluable contents of these institutions obviously interfered with normal working in the departments. Yet in these museums good progress was made, both in the development of the exhibited collections and in the less spectacular research conducted in the laboratories. That this work should now have been brought almost to a stop is regrettable, if inevitable. The announcement recently made that certain galleries are to be reopened to the public, and that special exhibits of current interest are being arranged, will be widely welcomed.

Biology in Schools

THE latest report of the Joint Committee of the Four Secondary Associations shows useful and, indeed, necessary work for education in the way of criticism, protest and suggestion. Complacency about the success of evacuation is now being reduced. Authorities who commandeer schools for officials and leave school buildings in a defective state have much to answer for. Such unwise economy is strange, after reckless expenditure elsewhere. A subsidiary subject syllabus is printed which a sub-committee of biologists has suggested for a London Higher School Certificate, since separate syllabuses for botany and zoology are regarded as unsatisfactory. This scheme for biology includes six important subjects, from histology to heredity and ecology, though the last-named is reduced to the study of fauna and flora in a restricted area. A practical examination and a written paper, each for three hours, are proposed, but the former, if ill-done, will not mean failure in the subject as a whole. The wide ground is well covered but, as the average teaching time for the whole of the syllabus, including practical work, is three hours a week, is there not too much to get through ? Ambitious programmes tend to produce shallow knowledge which is soon lost.

Cave Man in Colorado

EXCAVATION of a cave near Durango, Colorado, it is anticipated, may afford evidence for an approximate early dating of basket-maker culture in the southwestern States. The investigation was carried out on behalf of the Carnegie Institution of Washington by Earl H. Morris. Evidence of occupation, according to a report circulated by Science Service of Washington, D.C., was found below three feet of accumulated debris. There were indications that the inhabitants had lived in one-room structures, with mud-coated floors and fire-pits, though how these constructions were built was not detected. Corn and pumpkins were grown, but the principal mode of subsistence apparently was by hunting.

The most significant find, however, consisted of charcoal, from which tree-ring sequences have been constructed each covering a period of at least one hundred years. These are not only independent of one another, but also of any known Indian tree-ring datings. As these last have now been carried back to about A.D. 150, unless, as Dr. A. V. Kidder has suggested, conditions in this area were entirely different from the normal for northern Colorado, this constitutes valid evidence for Basket-maker occupation of the cave at not less than approximately two thousand years ago.

A Preparation for the Control of Bleeding

A FAT-SOLUBLE vitamin, known as vitamin K, is indirectly concerned with blood coagulation, will reduce the clotting time of blood in cases of prothrombin deficiency, and will check certain forms of hæmorrhage, such as occur in obstructive jaundice and occasionally in new-born babies. Vitamin K is found naturally in alfalfa and hog's liver fat, it has been isolated and its chemical composition determined. Several related but simpler compounds are known possessing a physiological action similar to the natural vitamin K, and one of these—a methylnaphthaquinone—has been introduced for use in medicine by Glaxo Laboratories, Ltd., Greenford, Middlesex, under the name "Kapilon". Kapilon has been found to be a valuable agent for reducing bleeding in obstructive jaundice and in neo-natal hæmorrhage.

Institution of Electrical Engineers: Scholarships

THE following scholarships are open for award by the Institution of Electrical Engineers during 1940 : *Duddell Scholarship* (value £150 per annum, tenable for three years), open to British subjects less than nineteen years of age on July 1, for a whole-time day course in electrical engineering ; *Ferranti Scholarship* (value £250 per annum, tenable for two years), open to British subjects less than twenty-six years of age on July 1, who are students or graduates of the Institution, for whole-time research or post-graduate work of an electrical engineering nature ; *Swan Memorial Scholarship* (value £120, for one year), open to British subjects less than twenty-seven years of age on July 1, for whole-time research or post-graduate work of an electrical engineering nature ; *Silvanus Thompson Scholarship* (value £100 per annum and tuition fees, tenable for two years), for works' employees who are the sons of parents of limited means, open to British subjects less than twenty-two years of age on July 1, for a whole-time day course in electrical engineering at an approved university or technical college ; *William Beedie Esson Scholarship* (value £120 per annum, tenable for two years, renewable in approved cases for a third year), for works' employees who are the sons of parents of limited means, open to British subjects less than twenty-two years of age on July 1, for a whole-time day course in electrical engineering at an approved university or technical college. Further information can be obtained from the Secretary, Institution of Electrical Engineers, Savoy Place, London, W.C.2.

Royal Society of Edinburgh: New Fellows

THE following have been elected fellows of the Royal Society of Edinburgh : Mr. E. B. Ball, president of the Institution of Mechanical Engineers ; Mr. J. Bowman, City water engineer, Edinburgh ; Mr. B. S. Bramwell, advocate, London ; Mr. J. Brough, lecturer in vertebrate zoology, University of Edinburgh ; Dr. A. F. Buchan, teacher of mathematics, James Gillespie's School, Edinburgh ; Mr. J. M. Caie, deputy secretary, Department of Agriculture for

Scotland; Mr. J. Cameron, formerly head of the Pharmaceutical Department, Peiping Union Medical College; Prof. J. W. Cook, Department of Chemistry, University of Glasgow; Dr. J. Coutts, lecturer in pharmaceutics and demonstrator in practical pharmacy, St. Bartholomew's Hospital Medical College, London; Mr. Satchidinanda Datta, veterinary research officer, Imperial Veterinary Research Institute, Calcutta; Dr. T. Elder Dickson, art master, George Watson's Ladies College, Edinburgh; Dr. A. T. J. Dollar, assistant in the Department of Geology, University of Glasgow; Dr. H. I. Drever, assistant in the Department of Geology, University of St. Andrews; Mr. W. McC. Harrowes, medical director, New Saughton Hall Private Mental Hospital, Polton, Midlothian; Mr. T. Hart, collector of the Trades House of Glasgow; Prof. C. F. W. Illingworth, Department of Surgery, University of Glasgow; Mr. J. G. Kyd, registrar-general for Scotland; Mr. P. R. Laird, secretary to Department of Agriculture for Scotland; Dr. Robert McAdam, lecturer in mining and surveying, Heriot-Watt College, Edinburgh; Dr. J. A. Macdonald, lecturer in botany, University of St. Andrews; Dr. A. E. W. McLachlan, clinical medical officer, Newcastle General Hospital, Newcastle-upon-Tyne; Dr. A. MacNiven, physician superintendent, Royal Mental Hospital, Glasgow; Prof. G. F. Marrian, Department of Chemistry in relation to Medicine, University of Edinburgh; Dr. E. R. A. Merewether, H.M. medical inspector of factories, Birmingham; Mr. R. M. Neill, senior lecturer in zoology, University of Aberdeen; Dr. H. B. Nisbet, lecturer in chemistry, Heriot-Watt College, Edinburgh; Mr. J. S. C. Reid, solicitor-general for Scotland; Mr. H. Riley, founder and headmaster of Strathallan School, Forgandenny, Perthshire; Mr. J. Thomson, distiller, London; Dr. H. M. Traquair, president of the Royal College of Surgeons of Edinburgh, lecturer on diseases of the eye, University of Edinburgh.

Announcements

THE council of the Royal Society of Edinburgh has awarded the Keith Prize for the period 1937–39 to Prof. F. A. E. Crew, for his papers and joint papers in the *Proceedings* of the Society within the period of the award, and in recognition of his valuable contributions to animal genetics; and the Neill Prize to Mr. James Wright, for his important paper on "The Scottish Carboniferous Crinoidea", published in the *Transactions* of the Society within the period of the award.

THE Senatus of the University of Edinburgh has awarded the Cameron Prize to Prof. E. C. Dodds, Courtauld professor of biochemistry in the University of London, for his work on synthetic œstrogens.

THE Masters Memorial Lectures of the Royal Horticultural Society will be delivered in the lecture room of the Society's New Hall in Greycoat Street, Westminster, on April 2 and 16, at 3 p.m., by Prof. F. E. Weiss, on "Graft Hybrids and Chimaeras".

PROF. MAX BORN, Tait professor of natural philosophy in the University of Edinburgh, will give the distinguished visitor's address before the Royal College of Science Mathematical and Physical Society at the College on March 11 at 5.15. Prof. Born's address will be entitled "On Melting".

MR. T. T. PATERSON, curator of the University Museum of Archæology and Ethnology, Cambridge, will deliver the Swiney lectures on geology in the rooms of the Linnean Society on Fridays and Mondays, at 3 p.m., from March 29 until May 10 (April 19 excepted). The subject of the lectures, to which admission is free, will be "Geology and Early Man".

THE Committee on the Chemistry of Proteins of the Division of Chemistry and Chemical Technology of the National Research Council has been granted 3,600 dollars by Mr. Eli Lilly of Indianapolis, for the establishment of a National Research Council fellowship in protein chemistry. The fellowship has been awarded to Dr. I. Fankuchen, who will carry on X-ray research on proteins in the laboratory of Prof. B. E. Warren at the Massachusetts Institute of Technology.

THE twelfth International Congress of Psychology, which was planned to take place at Edinburgh in July 1940, has been postponed, though not abandoned. The invitation of the City and University of Edinburgh is not withdrawn, and the Local Organization Committee hopes that the Congress may still meet in Edinburgh when circumstances permit the continuation and completion of the preparations.

THE annual meeting of the Swiss Society of Internal Medicine will be held in Bern during May 18-19, when the following subjects will be discussed: the chemistry of vitamins and some enzymes, introduced by Prof. P. Karrer of Zurich; the hypovitaminoses in medical practice, introduced by Prof. Bickel of Geneva. Further information can be obtained from the president, Dr. Otto Roth, Kantonspital, Winterthur.

AN Argentine Society of Social Medicine has recently been founded at Buenos Aires.

A MONUMENT has been erected at Chateauroux, France, of Stanislas Limousine, the chemist, who invented wafers for unpleasant drugs and pipettes for counting drops, introduced coloured bottles for poisons, organized the first public laboratory, and first injected quinine hypodermically.

ACCORDING to an investigation carried out in Calcutta, more than 96 per cent of 887 maternal deaths were due to an avoidable factor. Puerperal sepsis accounted for 32 per cent, eclampsia for 18 per cent, hæmorrhage for 11 per cent, anæmia for 24 per cent, and septic abortion for 5 per cent. The chief cause of death from diseases associated with child-bearing was pulmonary tuberculosis, which accounted for 40 per cent.

LETTERS TO THE EDITORS

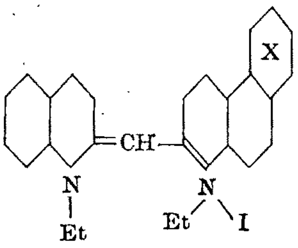
The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

IN THE PRESENT CIRCUMSTANCES, PROOFS OF "LETTERS" WILL NOT BE SUBMITTED TO CORRESPONDENTS OUTSIDE GREAT BRITAIN.

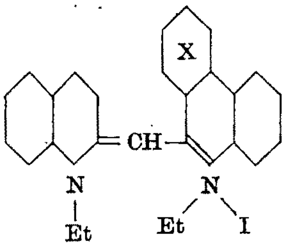
NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 391. CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Steric Influence in Optically Sensitizing Dyes

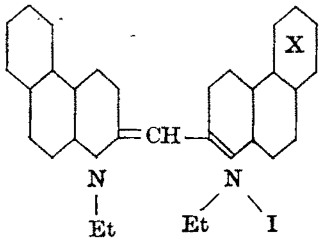
IN a paper by L. G. S. Brooker and C. H. Keyes[1], the preparation is described of certain isomeric cyanine dyes having the following formulæ :



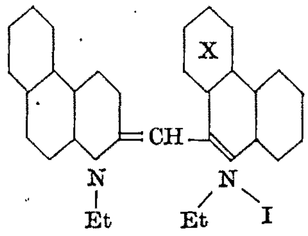
A



B



C



D

Brooker and Keyes noted that dyes *A* and *C* were strong sensitizers, while *B* and *D* did not sensitize. These substances were investigated later by J. A. Leermakers, B. H. Carroll and C. J. Staud[2], who confirmed the sensitizing results. But in addition they observed strong adsorption to gelatino-silver bromide grams of *all* the isomers, and "pronounced absorption maxima (by reflection)".

In recent work on these compounds we have observed, first, that the *rate* of adsorption to silver bromide from aqueous gelatin solution of dyes *B* and *D* is very much lower than for dyes *A* and *C*, although much the same adsorption densities (in molecules per unit area) were ultimately obtained. While this might account to some extent for lack of sensitizing (because of insufficient time of treatment), it does not appear an entirely sufficient explanation. A further complication was encountered in the form of a strong tendency of isomers *B* and *D* to bleach or fade, even in alcoholic solutions, probably by autoxidation.

On constructing the formulæ for these isomers, using correct bond angles and interatomic distances, it can be seen that complete coplanarity of the molecule is not possible in case *B* without bringing the 3,4-benzo-radicle within a distance of *ca.* 1·7 A. of the opposite quinoline group, and in case *D*, of the opposite β-naphtho-quinoline. This condition is not improved by 180° rotation of a nuclear group about a $=CH-CH<$ linkage to an alternate coplanar stereoisomer. The same condition obtains for 1,1′-diethyl-3′,4′-dibenzo-2,2′-carbocyanineiodide (having three methines between two phenanthridine nuclei), which was found also not to sensitize, but does not for 1,1′-diethyl-5,6,5′,6′-dibenzo-2,2′-carbocyanine iodide (having three methines between two β-naphtho-quinoline nuclei), which sensitizes strongly, and also not for 1,1′-diethyl-3,4,5′,6′-dibenzo-2,2′-carbocyanine iodide (having three methine groups between one β-naphtho-quinoline and one phenanthridine nucleus), and which definitely sensitizes.

On examining the absorption spectra (in alcoholic solution) of the non-coplanar isomers, it was observed that the half-width of the absorption band of maximum wave-length was much greater for the non-coplanar isomers than for their isomers, and the molecular extinction coefficients at $\lambda_{\max}$ were much less. There is also evidence that the yields are considerably lower than in synthesis of similar dyes which can readily assume a coplanar form of the fully extended (*trans-trans*) molecule.

It was suggested by Leermakers, Carroll and Staud[2] that "the phenyl group (*X*) in dyes *B* and *D* interferes with the proper exchange of energy between dye and silver halide, because of some steric effect in the molecule". The steric effect we believe to be the inhibition of coplanarity (cf. for analogous cases C. J. B. Clewes and K. Lonsdale[3], also J. M. Robertson[4]) of the dye molecule, and consequent interference with its resonance. In a fuller account the relation of coplanarity to adsorption (cf. Sheppard, Lambert and Walker)[5] will be discussed, as well as the temperature influence. The steric factor here indicated is of far-reaching importance in regard to the effects of substituents in the polymethine dyes.

Gattermann Synthesis of Aldehydes

The observation was made recently that hydrogen cyanide promotes the growth of certain fungi[1], which indicates the increased activity of the enzymes present in such circumstances. Earlier findings, on the other hand, had had some bearing on the mechanism of the mixed Cannizzaro reaction[2]. Investigations are now being carried out in this laboratory, in an attempt to contribute toward the elucidation of the mechanism of the Gattermann synthesis of aldehydes[3].

These experiments involve an adaptation of the original technique, using aluminium chloride, sodium cyanide (both chemically pure and "Aero Brand"), a solvent belonging to one of several series of hydrocarbons, and dry hydrogen chloride. They have already proved the practicability of this method[4]. The yields thus far obtained are evidenced by some data presented in the table below.

At the same time, the use of solvents belonging to homologous series has already outlined the basis of a rule relating the position of a given solvent in such a series to the yields obtained. The table, illustrating the results of an average series of trials, will serve to exemplify the latter point:

Formula of solvent	Name	C-atoms in side chain	Average yield %
PhH	Benzene	0	11
$PhCH_3$	Toluene	1	20
$PhCH_2CH_3$	Ethylbenzene	2	38
$PhCH(CH_3)_2$	Cumene	3	24
$PhCH(CH_3)(C_2H_5)$	sec.-Butylbenzene	4	3·5
$PhC(CH_3)_2(C_2H_5)$	tert.-Amylbenzene	5	7·5

Further investigations are in progress along several lines (including the influence of directive substituents), with a view toward clarifying some of the less evident features of the Gattermann synthesis.

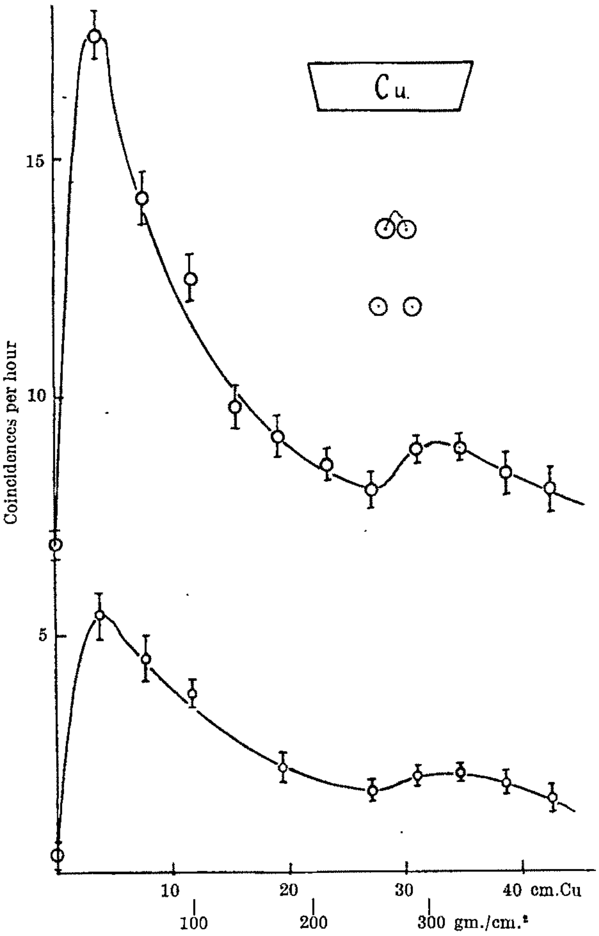
The Second Maximum in the Rossi Transition Curve for Copper

K. Schmeiser and W. Bothe found a pronounced second maximum in the transition curve for cosmic ray secondaries from large thicknesses of lead. This maximum became the more pronounced the smaller the angle subtended by the counters at the absorber. W. Morgan and K. Nielson, on the other hand, found no indications of a second maximum for a counter arrangement similar to that employed by Schmeiser and Bothe, with the exception that the two upper counters were not joined together, while a rather similar curve to that of Schmeiser and Bothe was obtained when the upper counters were linked together. In this case the background rate was very much increased. This appears to show that the relatively high count under large thicknesses is connected with a high background rate.

In view of the fact that these two experiments are not in harmony, it was considered worth while to investigate the small-angle showers under large thicknesses of material, both when the upper counters are joined and when they count separately. The absorber used was copper, the angle subtended by the counter system at the absorber 6°. The curves obtained in the two cases are shown in the accompanying graph. When the upper counters were connected the background rate was certainly increased very much, but the characteristics of the curves remained essentially the same at large thicknesses. Both show a marked second maximum.



In the case where the upper counters work separately, and fourfold coincidences are counted, the number of counts without copper is very small, that is, the background rate is very small. Threefold coincidences, with the upper counters joined, show, on the other hand, a large background rate. The conclusion is that it is not the background rate which is responsible for the relatively high count at large thicknesses, but the secondaries from the material placed above the counters.

Electronic Specific Heat of Graphite

In a previous communication[1] it was shown that the observed large diamagnetism of graphite along its hexagonal axis is that of its 'free' electrons, and is of the Landau type. At high temperatures it conforms to the Curie law $K = - n\mu^2/(3\ kT)$, and at low temperatures it tends to the temperature-independent value $K = -n\mu^2/(2\ kT_0)$, where n, the number of free electrons, is found to be just one per carbon atom, and T_0, the degeneracy temperature, is found to be about 520° K.; μ is the Bohr magneton.

These results fit well with the known electronic structure of graphite. From structural considerations we should expect one electron per carbon atom to be free, and its freedom of movement to be confined to the basal plane. This restriction of the freedom to the basal plane, besides directing the whole of the diamagnetism of these electrons along the normal to the plane, will also make the spacing of the energy levels of these electrons very narrow, and the degeneracy temperature very low, as required by observation.

This number of free electrons, namely, one per atom, together with the very low degeneracy temperature of the electron gas, should make the electronic specific heat of graphite at room temperature, and at low temperatures, much larger than that of most metals. Now the electronic contribution is most easily evaluated at very low temperatures, where the contribution from the lattice becomes relatively small. The available experimental data[2] for graphite extend down to about 29° K. only, and from these data the electronic part of the specific heat at low temperatures may be estimated roughly as 20×10^{-4} T. cal. deg.$^{-1}$ per gm. atom. This is more than ten times the electronic specific heat of copper or silver, and is of nearly the same magnitude as that of the transition metals, nickel, platinum and palladium.

It appears that even at 40° K. the electronic contribution to the specific heat of graphite greatly predominates over the contribution from the lattice.

Effect of Synthetic Vitamin B_6 on the Hæmopoietic System of Human Beings

Since vitamin B_6 (2-methyl, 3-hydroxy, 4,5-di-[hydroxymethyl] pyridine) is a constituent of liver and yeast, both of which relieve some of the symptoms of pellagra and pernicious anæmia in relapse, it was decided to give large amounts of this synthetic vitamin to pellagrins with macrocytic anæmia and to patients with classical pernicious anæmia. The observations of Fouts, Helmer, Lepkovsky and Jukes[1] show that dogs with a deficiency of vitamin B_6 in the diet develop a hypochromic anæmia which is not relieved by iron. These results have been confirmed and extended by McKibbon, Madden, Black and Elvehjem[2] in puppies. We have searched in vain to date for patients with hypochromic anæmia which did not respond to large amounts of iron. The vitamin B_6 used throughout this study was furnished by Merck and Company, Rahway, New Jersey.

The present report is concerned with the effect of the intravenous administration of from 50 to 100 milligrams of crystalline vitamin B_6 in sterile physiological solution of sodium chloride, each day for a period of ten days, to three pellagrins with macrocytic anæmia and to two patients with pernicious anæmia. Within forty-eight hours, the patients with pellagra and pernicious anæmia experienced considerable increase in sense of well-being and strength. On the fifth, sixth, seventh and eighth days of the study, in every instance, a slight but definite reticulocytosis appeared. The reticulocytes did not rise above five per cent, but the white cell count, which was extremely low in the two patients with pernicious anæmia, increased strikingly during the period of reticulocytosis. This increase was principally in the polymorphonuclear leucocyte series. One hundred milligrams of vitamin B_6, incubated with 100 c.c. of normal fasting human gastric juice, was given orally to one of the patients with pernicious anæmia after reticulocytes and white blood cells had reverted to the original low level, with a response identical to that observed following the administration of vitamin B_6, intravenously.

These findings suggest that vitamin B_6, when administered in large amounts, has a definite effect upon the hæmopoietic system of human beings who have macrocytic anæmia of pellagra or pernicious anæmia in relapse. This substance does not, however, in our opinion, act specifically either as the true anti-pernicious anæmia factor or as the extrinsic factor of Castle.

This study, an account of which was read before the Academy of Medicine of Cleveland, December 15, 1939, was aided by grants from the John and Mary R. Markle Foundation and Anheuser-Busch, Inc.

Effect of Stilbœstrol on the Ovaries of Hypophysectomized Rats

Various authors have reported that small doses of œstrogen injected in the intact adult rat cause an increase in ovarian weight, generally attributed to an increase in the secretion of luteinizing hormone from the pituitary[1].

Comparatively large œstrogen dosage causes a decrease in ovarian weight in the intact animals. The available evidence strongly suggests that this is due to a depression of hypophyseal activity[2]. So far as can be ascertained, however, little work has been done on the action of œstrogens on the ovaries of the immature hypophysectomized rat, though such a preparation should give valuable information about the direct action of œstrogens on the ovary. Accordingly, immature (40–50 gm.) female rats were hypophysectomized and a solid tablet of œstrogen was implanted subcutaneously two days after operation. The œstrogen used was the synthetic compound diethylstilbœstrol[3]. Two important effects were observed: first, that the œstrogen tablet prevented or greatly retarded the atrophy of the ovary that normally occurs after hypophysectomy, and secondly, that the response of the ovaries to the injection of pregnant mare serum was markedly increased with more pronounced luteinization of the membrana granulosa. Pregnant mare serum is mainly follicle-stimulating in action and has a much greater gonadotrophic action in intact immature rats than in hypophysectomized rats[4]. The tests on this substance were carried out as previously described[4], the animals being killed fifteen days after operation. The results are summarized in the accompanying table.

Condition of rat and treatment	Without œstrogen		With œstrogen	
	Mean wt. of ovaries (mgm.)	No. of rats	Mean wt. of ovaries (mgm.)	No. of rats
Normal	11·6 (10-13)	5		
Hypophysectomized 10–15 days post-operative	3·6 (2–7)	13	9·0 (6–15)	9
10 mgm. *PMS* 10	42 (27–59)	4	112 (79–168)	3
29 mgm. *PMS* 10	71 (57–95)	5	202 (106–250)	3
2·5 ml. *PMS* 11	35 (24–46)	5	81 (52–97)	3

PMS 10 is a concentrated extract of pregnant mare serum diluted with lactose, *PMS* 11 is a sample of pure serum diluted five times.

While it would be premature to speculate on the wider implications of these results, it is obvious that no action on the pituitary gland can be involved nor can the maintenance of corpora lutea play any part, since they are absent in the immature rat ovary. It is also clear that the role taken by the pituitary in the greater response of normal rats to gonadotrophic stimulation compared with the response in hypophysectomized rats will have to be reconsidered. It should be emphasized that the dose of stilbœstrol absorbed (as measured by weighing the tablets before implantation and at autopsy) was large, being 150–200 µgm. per day. This dose is much larger than any previously used in this connexion[5]. It is interesting to note that even these large doses did not produce any increase in the ovarian weight for normal animals of this size, so that œstrogen cannot be regarded as strictly gonadotrophic in the usual sense of the term.

Experiments are in progress to give more detailed information regarding the quantitative relations and histological changes of the œstrogen effect, and to test the reaction with other gonadotrophins.

Experiments in Non-Sensory Cognition

Two independent researches in this field have recently yielded mutually supporting results of considerable interest.

One of us (W. W. C.) used simple drawings as test material. In order to exclude processes of rational inference, and coincidental thinking, the subjects for these were selected by a random method immediately before each trial. Fifty such 'originals' were used, in five experiments of ten originals each. About 250 percipients took part, of whom none was ever in the same room as an original during a trial. In nearly all cases the original was put up in the experimenter's study and the percipients recorded their impressions, mainly by drawing, in their own homes. The whole of the material thus obtained (about 2,200 drawings) was marked against all fifty originals by a judge who had not been concerned in the experiment and did not know which original was which. Thus there was no possibility of the percipients inferring the probable nature of the original, or of their knowing it by sensory means, or of the judge's predilections biasing the outcome.

It was found (*a*) that percipients scored significantly more 'hits' (resemblances) on originals of experiments in which they were working, as compared with the originals of experiments in which they were not working, than would be expected on the null hypothesis that there is only a chance connexion between the originals used and the drawings produced ($P < 0{\cdot}0001$); and (*b*) that 'displacement' occurred to a significant extent; that is to say, 'hits' were not necessarily made on the same occasion as that on which the original concerned was displayed, but might be early or late, though most frequent on or near the occasion of display.

The other of us (S. G. S.) used specially randomized packs of cards, of which each bore one of five different symbols which percipients were required to name, under experimental conditions very carefully devised to exclude completely the 'leakage' of sensory clues to the percipient. A total of 128,350 guesses in 5,134 'runs' of 25 each was collected from 160 percipients. In 57,450 of these, the experimenter looked at the card while the percipient was guessing; in the remaining 70,900 cases he did not. The results at first sight were null, for in the first series the excess of successes over the expected number was only 51, which is less than the standard deviation, and in the second there was a deficiency of 160, which is only 1·50 times the standard deviation.

The discovery of a displacement effect, as recorded above, however, suggested a possible reason for the failure to score, namely, that percipients' guesses might refer to cards a few places before or after the one at which they were aimed. It was accordingly decided to examine the number of hits made on cards 1, 2, 3, etc., places before and after the guess.

As a start, two percipients, one of whom had done 2,000 guesses and the other 800, were scored in this way up to a displacement of eight positions in each direction. In the first case, the three central positions show an excess of 178 hits over expectation, equivalent to 5·82 times the standard deviation, giving $P < 10^{-8}$; in the other, the excess is 86·8, or 4·49 times the standard deviation, giving $P < 10^{-5}$. Either of these gives a highly significant result, even if taken as the best sample of the whole material.

Thus the results of the card-guessing experiments confirm the displacement effect discovered in the experiments with drawings; and these have led to a type of effect in the card-guessing being brought to light which might otherwise have escaped notice.

Full substantiatory details of both investigations will be published shortly.

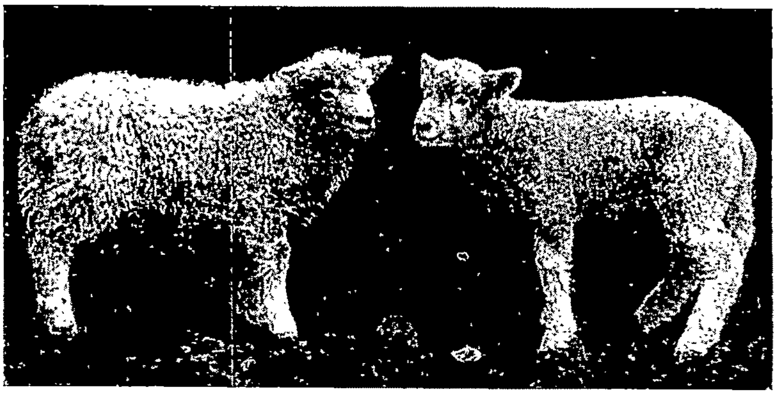
A Mendelian Situation in the Birthcoat of the New Zealand Romney Lamb

In our work on the inheritance of the abundance of halo-hairs in the birthcoat of the New Zealand Romney lamb, interest has become centred in a genetic situation which we find ourselves a little surprised to encounter in a character of a marketable product of livestock other than colour. While complexities are not lacking, it is plain that we are dealing with something more clear-cut than the usual multifactorial flock of factors defying genetic analysis.

Lambs with gross abundance of halo-hairs on the main area of the body, as well as on the extremities, are reported by breeders to make their appearance from time to time. It is safe to say, however, that they are not very common. These 'gross' lambs we call N-type, N being the initial letter of the name of the breeder, Mr. N. P. Nielsen of Tiakitahuna, who gave us our first ram of the type in question. In several N-type lambs born in various experimental matings, it is concluded from their ancestry and/or breeding performance, that the genetic basis is multifactorial, but in most N-type lambs born at the College the genetic basis is manifestly relatively simple. This is a summary of our findings from experiments in which well over a hundred N-type lambs have been produced.



Left: N-type; right: not-N-type. The latter had no halo hairs on the main area, but many not-N lambs have some halo-hairs there, even large numbers, but characteristically fewer than N-type. These lambs are twins. The father was N-type, the mother not-N, with no halo-hairs. The sire of the father was N-type, the dam of the father had no halo-hairs.

(1) Breeding results from two N-type rams, not related to one another, together with results from rather numerous N-type descendants of theirs, make it look as if this kind of coat were conditioned by a single dominant factor linked with the sex-influenced factor for horns, with crossing-over occurring about once in ten or twelve times.

(2) Some attention has been paid to horns by one of us (J. A. S.). It happens that horns have been rather plentiful in non-N experimental stock. On the average the horns are decidedly bigger in N-type than in non-N rams.

(3) Several pieces of evidence indicate that this N factor (or possibly N complex) sometimes comes to incomplete expression, so that the lambs fall a little short of the abundance of halo-hairs regarded as properly gross. It may suffice to mention the following two points:

(a) In back-crosses of horned N-type rams deemed double heterozygotes, most of the near-N male offspring have horns.

(b) Most of the ewes chosen for back-crosses had few or no halo-hairs on the back. The lambs could be separated almost sharply into two groups, those of the N-type and near-N-type and those with few or no halo-hairs on the back. There were very few with intermediate abundance of halo-hairs.

(4) In back-crosses of heterozygous N-type (so regarded from their parentage) to not-N, some ratios are almost exactly 1 : 1, but in the offspring of some tested rams there is a deficiency of N-type, that is, an excess of lambs definitely not-N. Whether this deficiency of N-type is significant, and how it is to be interpreted if it is real, are matters calling for further experiment.

(5) One N-type ram, with all his parents and grandparents not-N, was mated with not-N ewes with no, or few, halo-hairs on the back. He sired 3 N-type, 1 near-N, and 60 not-N. So far he has been mated with only four of his own daughters (all not-N), getting one of the N-type lambs and the near-N lamb just mentioned, and 2 not-N. One of the other N-type lambs was from a daughter of one of our original N-type rams.

(6) (a) A not-N ram sired by the original Nielsen ram was mated with not-N ewes sired by the same ram. He gave 10 lambs, all not-N.

(b) A not-N ram (without any halo-hairs on the back), the son of an N-type son of the original Nielsen ram, was mated with not-N ewes (with no or few halo-hairs on the back), daughters of the original ram or one or other of his N-type sons. The result was 2 typical N-type, 9 not-N with halo-hairs absent or of low abundance on the back.

We are able to suggest more than one somewhat elaborate explanation of our list of facts. Two linked complementary factors for N-type are favoured by one of us (P. R. McM.), while a dominigene is the pivot of another hypothesis. We are reminded of the recent work on another domestic animal by Kurzbauer and Marchlewski, who find that "two yellow dogs may produce black offspring and two black ones may produce yellow"[1].

Air Transport, Insects and Disease

I HAVE read with much interest Dr. A. D. Imms's review (in NATURE, January 13, p. 76) of Mr. Sarel Whitfield's paper entitled "Air Transport, Insects and Disease", and agree with both the author and the reviewer that the present position of this problem is still unsatisfactory.

In Dr. Imms's opinion, "no adequate and reliable control of insects in aircraft has been discovered", which is true of insects in general, but is scarcely so of the class of insects to which he especially refers, namely, the carriers of malaria and yellow-fever. The evidence brought forward in our paper[1], supported as it was by the opinion of reliable observers, shows that adequate control of mosquitoes in aircraft can be effected if the measures devised by us, and by Dr. Park Ross, are carried out.

The reason why these measures have not been generally adopted is, first, because the provisions of the International Sanitary Convention on Aerial Navigation place the responsibility for insect destruction on the ground sanitary authorities of the various countries through which the aircraft passes; and secondly, because these local Governments are averse to delegating their responsibility under the Convention to aircraft companies, with the result that a variety of different insecticides is still being used, and the manner of their application is equally varied.

Dr. Imms's criticism is valid when applied to some other arthropods, and we have had correspondence recently regarding the possible carriage in aircraft of the cotton boll worm and of the Japanese beetle. We realize that the procedure devised for mosquitoes would be entirely ineffectual when applied to such parasites, and eminent entomologists, both at home and abroad, have been asked to advise us regarding a substance lethal to these arthropods and yet of practical application in a passenger-carrying aeroplane.

Until such a preparation has been found, it is obviously impossible for aircraft companies to proceed in the matter. We consider that we have a method, adequate and trustworthy, against mosquitoes; but until the biochemical side of the problem has been extended, we cannot take measures to destroy the more resistant parasites which may carry veterinary or agricultural disease.

If Mr. Whitfield's valuable monograph, and Dr. Imms's review of it, serve to direct attention to the nature of the problem awaiting solution, they will have done a great service to aerial transport.

Points from Foregoing Letters

THE presence of steric inhibition of coplanarity in certain polymethine (cyanine) sensitizing dyes is discussed by S. E. Sheppard, R. H. Lambert and R. D. Walker. It is adduced as a cause of modified spectral absorption and inefficiency of optical sensitizing of silver halides.

A. G. Mistretta and F. F. Nord describe experiments and give indications of a rule with regard to the relation between solvent and yield in the Gattermann synthesis using sodium cyanide.

P. J. G. de Vos finds a second maximum in the curve for cosmic ray secondaries from copper similar to that observed by other workers using lead.

In view of the large number of 'free' electrons present in graphite, namely, one per carbon atom, and the very low degeneracy temperature of the electron gas, indicated by the magnetic data, it is pointed out by K. S. Krishnan that the electronic specific heat in graphite should be much larger than in most metals. The available experimental data support this conclusion.

It is known that both liver and yeast relieve some of the symptoms of pellagra and pernicious anæmia, and also that both contain vitamin B_6. R. W. Vilter, H. S. Schiro and T. D. Spies have administered heavy doses of this vitamin, intravenously and orally, to patients suffering from pellagra and pernicious anæmia, with beneficial results.

P. C. Williams states that the atrophy of the ovaries that follows hypophysectomy may be prevented, in the immature rat, by the implantation of a tablet of the synthetic œstrogen stilbœstrol two days after the operation. The ovaries thus maintained respond to the injection of pregnant mare serum, both quantitatively and qualitatively, much more like the ovaries of intact rats than like those of untreated hypophysectomized rats.

W. W. Carington and S. G. Soal, working with simple drawings and with special cards respectively, under the most rigorous possible conditions, find significant cognitive relationships between the test material and the guesses made. In the first case, percipients score more hits on the drawings used in the experiment in which they were concerned than on those of other experiments; in the second, two sample percipients have been found to score heavily above expectation on the three cards preceding, coinciding with and following the guess, taken as a group.

Certain lambs of the New Zealand Romney breed are born with great abundance of so-called halo hairs in the fleece. F. W. Dry, P. R. McMahon and J. A. Sutherland have examined this condition genetically. Mendelian inheritance of the character is indicated, but no agreement has been reached as to the factors and mechanism concerned.

The Chief Medical Officer of Imperial Airways, Ltd., writes to confirm a comment made by Dr. A. D. Imms that the present position with regard to air transport in its relation to the transmission of disease by insects is unsatisfactory. He states that satisfactory measures against mosquitoes have been devised, but are not generally adopted because the responsibility for taking action is in the hands of the ground sanitary authorities instead of the aircraft companies. Measures against insects other than the mosquito are being sought.

RESEARCH ITEMS

Mangarevan Archæology

IN the course of the expedition to the Mangarevan Islands of the Bernice P. Bishop Museum, Honolulu, under Dr. Peter H. Buck in 1934, an archæological survey of sites on Mangareva itself as well as of stone structures on neighbouring atolls was made by Kenneth P. Emory (*Bull.* 163, Bernice P. Bishop Mus. 1939). Owing to the use of the stone for building by missionaries all important structures in the Mangarevan group have now disappeared; but fortunately the stone structures left by the Mangarevan inhabitants of Temoe atoll, 25 miles to the south-east, are intact. Here the largest structure is a platform 21 feet wide and 58 ft. long. It has an unenclosed court on the inland side extending 30 feet from the face of the platform. Across the court face are two high steps. The largest structures in Temoe had burials in small vaults at the top. In two maraes, open vaults at ground level are larger and more carefully constructed than the vaults containing burials. These, it has been reported, were considered the dwelling-place of the god of the marae. The nearest parallels to the Mangarevan maraes are certain image *ahu* of Easter Island, in which the platform is stepped on the court side, and at the top of which burials were made. The Easter Islanders added images of stone along the back of the platform. Probably the features shared by the Mangarevan and Easter Island structures had a common origin, possibly original features of Marquesan culture with which both Mangareva and Easter Island exhibit affinities, but which evidently have been modified in the Marquesan, where sacred structures are not uniform, nor of the type of Mangarevan and Easter Island sanctuaries. However, like the Easter Islanders the Marquesans set up large images on their sacred structures; but the Mangarevans lacked both the timber and the tuff which would have permitted the making of such images.

Toxicity of Snake's Venom

IT is the general impression, and has been definitely stated by workers in America and Australia, that snakes in captivity from which venom is repeatedly extracted gradually yield smaller quantities. and that the venom decreases in potency. These statements are not confirmed by the observations of N. O'Connor Wolff and Thomas S. Githens made upon a group of twenty-one water moccasins (*Agkistrodon piscivorus*), used for venom extraction over a period of two years (*Copeia*, 234; 1939). The 'milking' took place at irregular intervals, the longest time between extractions being six months and the shortest three weeks. The venom having been collected was measured, centrifuged to remove epithelial scales, and then dried either by gentle heat or in a desiccator under vacuum. Toxicity was determined by intravenous injection into pigeons of a solution of the dried venom to determine the minimum lethal dose. A table is given recording complete data regarding the extractions over the two-year period. At the earliest extractions the average amount of venom per snake on the first three occasions was 0·500, 0·486 and 0·517 c.c., while on the last three extractions the averages were 0·550, 0·777, and 0·722 c.c. Similarly the first minimum lethal doses averaged 2,000, 1,300 and 1,577 per snake, while the last three averaged 2,520, 1,970 and 2,500. The table shows a considerable range of fluctuation throughout the period, but seems to establish the contention of its authors that neither quantity nor toxicity decreased owing to repeated extractions.

Marquesan Insects

THE Pacific Entomological Survey, dealing in the main with the fauna of the Marquesas Islands, is a project organized and directed by institutions in Hawaii. As the result of expeditions sent out under its auspices a large addition to knowledge of the insects, and related arthropods, of the area concerned has been made. Under the title of "Marquesan Insects—III" published in 1939 as *Bulletin* 142 of the Bernice P. Bishop Museum, Honolulu, the latest contribution on the work of the Survey has come to hand and it marks the end of the present programme. The longer articles in the *Bulletin* are concerned with Crustacea (Talitridæ), Spiders, Acarina and Chelonethida. Among the insects themselves, the article on Scolytidæ by C. F. C. Beeson is of interest since it records the first known bark beetles from the Marquesas; more than two hundred specimens, representative of five genera and twenty-one species, were dealt with. Two new genera of Hydrometridæ, or water-bugs, are described by H. B. Hungerford, and a new Blastophaga from the indigenous Ficus of the Marquesas is dealt with by G. Grandi. Other papers on the Insecta include contributions by H. H. Knight on new species of the hemipterous family Miridæ.

Experimental Taxonomy

J. W. GREGOR (*New Phyt.*, 38, 293–322; 1939) has continued his analysis of wild populations by examining the differentiation of North American and European plantains. He shows that *Plantago maritima*, *P. alpina*, *P. carinata*, *P. juncoides*, and *P. oliganthus* of North America, Greenland, and Europe form an inter-fertile group which is diploid, while Alpine tetraploids form another group. He points out that variations within one sub-region overlap with those of another, but that the means of measurable characters within a population may differ from the mean of another population. Thus bracts and sepals of North American plantains are broader in proportion to length than those of northern Europe. The mean values of the sub-regions regarding this index and that of the ratio scape length to spike length show a gradient from low values in western America, rising in eastern America, Iceland, Faroes, Britain to a maximum in Sweden, and falling again in southern Germany. Data regarding various other measurable characters show similar geographical gradients, but it is important to note that irregularities in small localities sometimes occur. The author points out that classification founded upon the complex of characters in an individual is not so useful in experimental taxonomy as that of the average of characters in a population. The data illustrate the fact that growth and physiological characters behave in a similar manner to qualitative or morphological characteristics.

Diamond Deposits of Tanganyika Territory

Although diamonds have been worked in Tanganyika for sixteen years, no comprehensive publication covering the geological and economic aspects of the industry has appeared until now. *Bulletin* 12 of the Geological Division, T.T., by G. J. Williams, comes at an opportune time, just as the original finds are reaching the end of their productivity, since it gives an account of most of the country in which kimberlite (the home of the diamond) is known to occur, and provides a useful guide to prospectors in other areas. The kimberlite occurrences are mainly in the central granite batholith of Tanganyika. The individual pipes tend to be localized at or near geological contacts (for example, against dolerite dykes or remnants of basement rocks) or fracture zones. There are, however, groups of pipes without visible connexion with pre-existing structures, owing—at least in part—to the existence of thick covers of superficial deposits. Here the search for such minerals as ilmenite, garnet and zircon in the subsoil is most likely to lead to the body of kimberlite from which they were derived. Areas likely to repay prospecting are suggested. From evidence in Tanganyika alone, the age of the kimberlite masses cannot be determined exactly. They are, however, pre-Pleistocene and post-early Jurassic; a time-range within which falls the late Cretaceous age established for the South African pipes. The *Bulletin* contains a map of the kimberlite province of Tanganyika and also a map showing the distribution of kimberlite pipes and fissures throughout Central and Southern Africa.

The Quetta Earthquake of 1935

This earthquake has been studied in some detail by K. R. Ramanathan and S. M. Mukherji of the Colaba Observatory, Bombay (*Rec. Geol. Surv. India*, 73, Pt. 4, 483–513; 1938). It will be recalled that damage was caused by this earthquake along a tract of land extending from Baleli just north of Quetta, through Dingar and Mastung to Mand-i-Haji, and including the Shirinab Valley to the west of the Mastung–Kalat Road. It is an area about 68 miles long and 16 miles wide. The surface crack extended from about 30·3° N., 66·9° E., to 29·1° N., 66·5° E., the centre of the region of maximum disturbance being 29·7° N., 66·7° E. The seismological data used for the present study were the seismograms from Bombay, Agra, Calcutta, Hyderabad and Kodaikanal in India, together with fifteen seismograms from foreign observatories. Miss Bellamy, of Oxford, supplied readings from 142 observatories. From these data the authors concluded that the best position for the epicentre was 29·6° N., 66·5° E., slightly to the southwest of the permanent maximum displacement but well within the region of maximum macroseismic effects. The origin time of the earthquake was May 30d. 21h. 32m. 58·5s. G.M.T. Among the prominent features of the seismograms were the gradual increase of amplitude interrupted by larger and larger impulses, and the large amplitudes of the long waves compared with those of the preliminary phases, suggesting block movement and a shallow depth of focus (less than 10 km.). This was also deduced on other grounds. The energy of the earthquake was estimated to have been about 10^{21} ergs. or 1/2,000 that of the Great Assam earthquake of 1897. A list of aftershocks recorded at Agra is given.

Viscosities near Absolute Zero

With financial aid from the Smithsonian Institution, Prof. W. H. Keesom and G. E. Macwood have determined the viscosities of liquid helium and hydrogen and of hydrogen vapour at temperatures near the absolute zero (*Leyden Comm.*, No. 254). Their method is that of the oscillating disk, which is 5 cm. in diameter and is suspended by a phosphor bronze wire of 0·05 mm. diameter and 25 cm. long in a cylindrical box of a little greater diameter, the top and bottom plates of which can be placed at various distances from the disk. The decay of the torsional oscillations of the disk were observed by the mirror, telescope and scale method. The apparatus was standardized by using in it helium gas of known viscosity. The viscosity of hydrogen is normal in both states. For the liquid it decreases from 210 micro-poise at 15° K. linearly to a little more than 150 at 18° K., then more slowly to 140 at 20° K. For the vapour it increases from a little less than 10 micro-poise at 14·5° K. to 13 at 21° K. linearly, and is independent of pressure. The viscosity of liquid helium is abnormal. It increases from 1·8 micro-poise at 1·3° K. at first slowly, then rapidly to 17·5 at 2·1° K., where there is some uncertainty. From this point it increases to 25 at 3° K. and to 29 micro-poise at 4° K.

Observations of the Zodiacal Light

Mohd. A. R. Khan, Begumpet, Deccan, has sent a description of his observations of the zodiacal light on December 17, 1939, at 5.30 a.m., Standard Indian Time. The phenomenon produced the impression of two cones, one within the other, the inner cone being the brighter of the two. The apex of the inner cone rested on γ Virginis, and ξ Virginis, β Libræ and μ Serpentis lay approximately on its northern boundary. On the southern boundary were 76 Virginis, 20 Libræ, and φ^1 and φ^2 Lupi. The apex of the outer cone appeared to extend to ρ Leonis, and 109 Virginis and π Hydræ were on its northern and southern boundaries, respectively. The light thus presented the appearance of a tall double cone, broad at the base near the horizon, and getting quickly narrower and narrower towards the apex. A similar configuration was observed on December 12 at 5 a.m.

Structures of Sulphuryl and Thiophosphoryl Fluorides

As the relations between bond length and bond character are not well understood for molecules containing semipolar double bonds, the investigation of SO_2F_2 and PSF_3 by the electron diffraction method (D. P. Stevenson and H. Russell, *J. Amer. Chem. Soc.*, 61, 3264; 1939) is of interest. The distances predicted by the standard covalent radii are P–F 1·74 A., P=S 1·95 A., whilst those found are 1·51 and 1·85, indicating resonance with a larger proportion of ionic structures than for the corresponding chlorine compound, and due to a considerable triple bond character made possible by the large electronegativity of fluorine and the small difference in electro-negativity between phosphorus and sulphur. The relatively small angle 99·5° F–P–F is not interpreted for lack of data. The S–F distance in SO_2F_2 is 1·56 A., which is less than the single bond distance calculated from the standard covalent radii, but the shortening is not so great as is found with the fluorine derivatives of phosphorus. Although there is much more shortening in the S–Hal bond in SO_2F_2 than in SO_2Cl_2, the S–O distance 1·43 A. in SO_2F_2 is the same as that in SO_2, SO_3 and SO_2Cl_2.

PREHISTORIC PEOPLES IN SOUTH AFRICA

DR. ROBERT BROOM'S recent discoveries in the Transvaal of important evidence bearing upon the origin and descent of man have tended to overshadow another field of anthropological investigation in South Africa which, though more localized in its application, ranks in African ethnology as scarcely of lesser significance for studies of the evolution and distribution of prehistoric racial types. The problem in question arises from the recognition by Dr. A. Galloway* in the skeletal material from the remarkable prehistoric sites of Mapungubwe and Bambadyanalo, recently excavated, of a new race, the Bush-Boskopoid, associated with and apparently responsible for the mining operations which figure conspicuously among the activities of the prehistoric inhabitants of Rhodesia. The physical characters of the race of miners, their relation to the Bantu-speaking peoples who later came to form the predominant population, and how far the Bush-Boskopoid of Mapungubwe constitutes the type, are discussed in a series of communications made recently to the Rhodesia Scientific Association (*Transactions*, 37; 1939).

In reference to certain human remains found in excavations at various times since 1934, which are recorded in detail by A. E. Phaup, the evidence of the prehistoric skeletal material as a whole from Rhodesia is summarized and discussed by Prof. M. R. Drennan.

By way of preface it is remarked that the remains, both male and female, appear to be those of indigenous natives living under tribal conditions, and using metals. They differ from the present Negroes of South, East and West Africa in that their skulls were longer and narrower than the average, their faces were more prognathous and their brains smaller. They were also shorter. They resemble the "Bush-Boskop" race of Mapungubwe and Bambadyanalo, and are similar to the more modern "Hottentot" type, seeming intermediate between Bush and Bantu, with some of the characteristics of both. They also show affinities to the Cro-magnon race of Europe. They buried their dead in caves and the ancient workings of prehistoric gold mines. The bodies were probably clothed or covered, and personal ornaments and small utensils were left on or near the body.

The remains were found in different conditions throughout Southern Rhodesia as follows:

Penhalonga. On the Umtali Mission Farm among a group of granite blocks and under the largest was a natural wedge-shaped cavity 50 ft. long and 20 ft. wide, which had been walled in. The floor was covered with bones and scattered groups of small beads of blue glass and ostrich-shell. Four skulls, three male and one female, were available for examination and were pronounced in a report by Dr. Drennan at the time to be "a good sample of some native group, . . . quite comparable to the existing groups of natives".

Makoni District. From a large limestone cave on Romsley extension farm came a human skull and tibia, animal bones, clay pots, grinding stones, a copper bangle and a spear-head. Dr. Drennan pronounced the skull to be female and "typically Bantu", closely resembling two Mashona skulls.

Carolina Claims, Mazoe. An almost complete female skeleton was collected by the late T. H. Wilson, of the Geological Survey, from the Carolina gold claims, about a mile south of Jumbo siding, in workings in a small hill of banded ironstone. The skeleton was found in reopening one of the old shafts. With it were eight rusty iron rings. Dr. Drennan's report states that the remains are those of a young female of native type aged about twenty years. The skull is comparable with that from Penhalonga, and "definitely negroid in every respect".

Eureka Mine, Sipolilo. Two fossilized fragments of a human femur were found in an ancient working of the gold mine. They show extreme degrees of platymeria and pilastering, features practically never occurring in this degree in Europeans, moderate in Bantu, but a marked feature of Bushman and Hottentot. A fragmentary skeleton of an infant found later, while indeterminate owing to age, is as regards the cranium typically 'negroid', while the mandible is definitely 'Bush-Boskop'.

Inyanga. Fragments of a skull from the Van Niekerk ruins, found lying under a large granite slab, apparently belong to a young female of about fifteen years of age. The measurements are very similar to those of the female from Penhalonga.

In his further review of the skeletal material from Southern Rhodesia as a whole supplementary to the report to which reference is made above, Dr. Drennan states that his interest in the ancient gold miners and other prehistoric inhabitants of Southern Rhodesia was first aroused by the skull from the Gwalo mine presented to the South African Museum by Sir Clarkson Tredgold in 1917. In this skull the features of Bushman, Hottentot and Bantu types are curiously and strikingly blended. Next came the skull from the Planet Mine, Bulawayo, which, while showing certain Bantu characters, is predominantly Bushman, and with reservation might be assigned to the Bush-Boskop group.

The material described by Mr. Phaup, though all legitimately prehistoric Rhodesian, falls into two groups—those with, and those without, a definite association with mining activities. In the mining group fall the Mazoe, the Eureka, and the Van Niekerk specimens; they all belong to the same physical type and are all women or children. The Makoni skull also belongs to the same physical group; but the group from Penhalonga seem to approximate more to the modern type.

While Dr. Drennan finds a considerable measure of agreement with Mapungubwe, there are also significant differences. The material from Mapungubwe and Bambadyanalo, to which Galloway applies the term Bush-Boskop, is not homogeneous, but includes three or four different elements. In the present series, however, there is no instance of the absolute long-headedness or big-brainedness of the Boskop race, so prevalent at Mapungubwe and Bambadyanalo, nor is their relative long-headedness to be accounted for as a mixture of Bushman and Boskop strains. For this we must look to a pre-negro strain. The pronounced prognathism of the present group emphasizes their negro character; but it is absent at Bambadyanalo.

It is thus impossible to reconcile the two findings at present; but it may turn out eventually that it is a difference between the exploiters of gold on one hand, who show a preponderance of Bush-Boskop character typical of the southern prehistoric peoples, and of the actual miners on the other hand, who show more negroid character inherited from northern pre-negro types such as Elmenteita man.

---

* Galloway, A., "The Skeletal Remains from Mapungubwe in 'Mapungubwe: Ancient Bantu Civilization on the Limpopo' ". Edited by Leo Fouché. Cambridge, 1937.

Upper jaws of a Boskop type attracted the attention of Prof. Raymond Dart in 1938 to the Cornucopia site at Rusape, Umtali, on which Mr. Barnes Pope had been engaged in trenching with the view of discovering the nature of the material there, which had attracted the ancient industrialists responsible for the workings of which evidence had been discovered. The appearance of a Boskop type was unanticipated as all previous skeletons from ancient workings in Rhodesia had been described as Bantu (Keith, 1931) or Bush (Drennan, 1930).

Mr. Barnes Pope, excavating in depressed areas with a luxuriant growth of trees and herbage, which had been disturbed on a grand scale at some past period of time, revealed consistently four layers: (1) the vegetation layer, (2) the gravel or barren layer, (3) the fertile layer, (4) the bed-rock layer.

The bed-rock layer consisted of granite boulders and the disintegrated granite which forms the basis of the area in which the ancient miners worked. The material which attracted them was either the rich brownish-black iron oxide grains, to be used either as a cosmetic or as a source of metallic iron, or alternatively the tin, which though not now found in paying quantities, may originally have been rich. This layer varies from three to forty-five feet.

The fertile layer, from which all objects found underground have come, varies from three inches to several feet in thickness but usually is only twelve inches in height. Here are crude potsherds, skeletal remains, beads, slag, a button of melted tin, etc. Curious arrangements of objects have been discovered. Under a flat stone were thirteen stone phalli. Here there were no bones; but in another place a skull was found accompanied by fifteen phalli. A second skull was found at a depth of fifteen feet, but without accompanying objects.

It may be inferred that two forms of burial were practised: (*a*) simple and sometimes phalli accompanied burials at the mining face, probably burials of miners; and (*b*) cylindrical stone monument burials in the 'mine-filling', probably burials of important individuals.

The 'mine-filling' process can be separated into two distinct phases represented by the sterile layer, composed mainly of earth displaced by the miners, and the vegetational stratum-humus, twelve to eighteen inches in thickness, representing the flux of a considerable period of time—certainly several hundreds and it may be even thousands of years. At Zuurberg the humid period represented by the black soil over the former land surface is dated tentatively at 1800 B.C.

This date, which applies to the earliest levels in which occur 'Bushman' burials on the Zuurberg site, is correlated by Wells with the "classical rainfall maximum" of C. E. P. Brooks (1922), dated at a period extending from 1800 B.C. to A.D. 500. The assessment of rate of deposition in South Africa, however, is notoriously difficult and uncertain. The period under investigation was one of aridity and erosion, rather than of precipitation. The rate of deposition of earthy vegetable layers at the present day in South Africa has not been determined; but while it would be rash to jump to the conclusion that the 12–18 in. earthy vegetable layer is referable to the same period as the Zuurberg material, the tentative suggestion of "even thousands of years" may be no exaggeration.

At the same time, cultural evidence from certain sources which have been under review may point to the later limits, for which an approximate dating might be suggested. While weapons and implements of iron are very similar to those collected on ancient ruins of medieval date, or even to those of the modern iron-worker, certain assemblages of beads are comparable to those of the Great Zimbabwe acropolies, that is, of the ninth to tenth centuries of our era, though here again allowance must be made for survival in fashion.

Turning to the skeletal material found on the Cornucopia site, L. H. Wells, in describing the two skulls, stresses their great length and relative narrowness. Thus the more complete of the two measures 201 mm. at its maximum length, while the maximum breadth is only 130 mm., giving a cephalic index of 65·0. The corresponding figures for the second skull are estimated at: maximum length, 190 mm.; maximum parietal breadth, 127 mm.; cephalic index, 66·5 approximately. The cranial capacities, respectively, are 1,425–1,500 c.c. and 1,300–1,350 c.c. In both, the bones are thick and massive and slightly mineralized.

The feature, however, which is singled out as especially noteworthy is the remarkable size of the palate and the teeth. In the first skull, the longitudinal and transverse diameters fall just within the maximum recorded for the South African Negro while the height of the palatal vault above the grinding surfaces of the teeth is greater than in any Negro. Moreover, the form is different, the incisors forming an almost straight line between the canines. The palate is thus quadrilateral rather than horseshoe-shaped. Except that it is much higher in the vault, this palate agrees with the Boskop type.

Both skulls agree in presenting very few negro features, while of their non-negro features, the majority are proper to the Boskop type.

Yet although these skulls recall the Boskop type, they also diverge widely from it. The significance of these findings becomes apparent on reviewing the skulls previously found in similar circumstances. The number found in Rhodesia is small. Skulls examined by Shrubsall and Keith were classified as of negro type, but probably these conclusions call for revision in the light of further knowledge. Galloway has recognized both Bush and Boskop features from Penhalonga. The Cornucopia find has revealed the association with an ancient occupation site of skeletal remains which are predominantly of non-negro type. They represent a type which there is good reason to believe preceded the Bantu-speaking Negro. Such a strongly marked Boskopoid type is already well known in the southern portions of Africa. The same elongated and low-vaulted skull has been found among the Hottentots and, it has been shown, can arise from the mixture of large-headed Boskop and small-headed Bush types. The most remarkable development of the last few years in South African anthropology has been the demonstration by Galloway (1937) that "a homogeneous Boskop-Bush population physically akin to the post-Boskop inhabitants of the coastal caves" was associated with the Iron Age civilization of Mapungubwe. It is concluded that the Cornucopia people, if not identical with the Mapungubwe type, are very similar in most respects.

A SLIDING RATE ELECTRICAL METER

IN a paper published in the *Journal of the Institution of Electrical Engineers* of January, Dr. Unz of the Iraq Petroleum Co., Ltd., has suggested a new type of electrical meter, to replace the existing maximum-demand indicators. The object of the maximum-demand indicators is to enable the supply station to charge its consumers not only in accordance with the number of electric units consumed, but also in proportion with the demand on the station at the time during which they were consumed. In the early days of the use of this system, the meter bill consisted of two components, the first being at a constant rate for all demands not greater than a certain minimum rate, and the second component being charged at a higher rate when the demand exceeded this rate. The object was to influence consumers to be economical with their lighting when they were consuming at the higher rate. Economy at these times is most important to the supply company, which is otherwise forced to buy large quantities of expensive reserve plant, used only for a short time every day when the demand is excessive.

Improvements to the demand-charging system have been effected by means of peak-load meters, load-levelling relays and time-switches, as well as by various refinements of the tariffs, but these are of limited application. A meter is required which would automatically fix the price level of each consumed unit as a function of the power at which it is applied, and integrate such prices to a total amount. The consumer would know that the price of a unit consumed at half load would be much lower than that consumed at double full load. He could therefore endeavour to reduce his electricity bill by improving the load factor to the utmost, but need never be afraid of being penalized for exceeding his usual demands. The supply undertaking, on the other hand, would have the full benefit of a rational and simple charging system, without the necessity of providing duplicate measuring instruments and wiring.

An integrating watt-hour meter having a curve for the speed characteristic instead of a straight line would serve the purpose. The meter readings would then not be in kilowatt-hours but in what might be termed 'key-units'. These readings would be proportional to the amounts of money due, as in load-rate prepayment meters or in double-tariff meters with a single counter train.

The speeding-up effect described above can be obtained in a meter either by making the driving torque proportional to a power of the load higher than the first, or by reducing the retarding torque of the brake. Dr. Unz states that the latter method is constructionally easier, and in addition it has the advantage that the existing driving elements with all their compensating devices can be left untouched. The constructional details of the proposed braking element are shown, its equivalent electric circuit is considered, and its performance discussed. The reconstruction of the meter characteristic is outlined, and the errors and compensation methods briefly discussed.

The device offers new facilities in the application of demand charges. It works on the same principle as a standard watt-hour meter, and deviates from the latter only in regard to its speed 'characteristic'.

THE MUSICAL PITCH OF ORCHESTRAS

IN the English edition of the second quarterly bulletin of the "Centro Volpi di Elettrologia" published in Venice last year, there is an interesting article by G. B. Madella surveying investigations which have been recently made on the frequency of the reference note of an orchestra. The history of this problem was discussed in an article in NATURE of November 5, 1938 (p. 820), by Dr. G. W. C. Kaye, who also described the proceedings of the international congress which made recommendations in 1939 (see NATURE, May 27, 1939, p. 905).

Madella describes a series of measurements made during a period of a month in the Electro-acoustic Department of the Istituto Elettrotecnico Galileo Ferraris in Turin at the request of the Italian Committee on Acoustics. Some of the results obtained are given below. A standard frequency of 400 was obtained from that of the institution standard, which operates at 1,000. This gives an accuracy quite sufficient for the purpose. The two tensions thus obtained having the unknown frequency and the frequency of 400 are then applied to a copper oxide modulator. The frequency beat obtained in this way is applied to the plates of an oscillograph and then registered by means of a photographic recording machine. The accuracy obtainable varies according to the time-length of the note studied; as a rule, it is about a tenth of a cycle. Attempts to apply stroboscopic methods were unsuccessful as these methods tire the eye of the observer and are therefore not suitable for systematic measurements.

The tuning frequency, on the average, was found to be above 435; during the transmissions of operas and symphonic concerts, values of the order of 441 were observed.

During the transmission of piano performances or of performances comprising pianos and vocal or string instrument groups, lower frequencies were nearly always observed, often in the neighbourhood of 435, with differences of less than 0·5 cycle. At a violin and piano concert the frequency most often heard was 437·1, but at a symphonic concert the frequency most frequently noted was 442, the maximum being 444·8 and the minimum 439·7.

The results are partly explained by remembering that when a piano is accurately tuned, the tuning is maintained without variations of practical importance. Wind instruments, even if well tuned at the beginning, have a tendency after a time to increase the frequency of the emitted note because of the heating produced by the breath of the player. Finally, string instruments allow the player within certain limits to follow the tune of other instruments, and the same is the case with singers.

No evidence was found to confirm the generally stated order of variation in which the mean tuning frequency tends to increase during the execution of selections by an orchestra. The frequency of the pitch which is observed during the tuning of instruments before starting the performance tends to be maintained as a mean value during the whole performance. As few tests of this have been made, it would be advisable to make further investigations; if confirmed, it would be of importance in relation to the choice of the steps apt to modify the tuning frequency.

TEMPORARY PRESERVATION OF ANIMAL SPECIMENS

MR. J. R. NORMAN, of the British Museum (Natural History), has abstracted and translated the following from a letter he has recently received from Dr. Paul Chabanaud, of the Museum National d'Histoire Naturelle, Paris:

On learning the news of the sensational discovery of *Latimeria chalumnae*[1], there can be, I imagine, few naturalists who were not seriously perturbed by the thought that it was only by the merest chance that this extraordinary living fossil was not irretrievably lost. Indeed, our congratulations are due to all those who have succeeded in saving this priceless specimen, although we must deplore the fact that its final state of preservation is so far from satisfactory.

Even if fishermen do not often find a representative of the Mesozoic fauna in their nets, how very few of the interesting specimens captured by them daily throughout the world find their way to our museums or laboratories. Even in the case of the species well-known to science, the larger individuals are rarely, if ever, preserved, and our knowledge of the size attained by certain animals (for example, the halibut—*Hippoglossus hippoglossus* (L.); some of the Siluroids; and very many Elasmobranchs) rests largely upon hearsay, or upon the examination of fragments (for example, the 'saws' of *Pristis*).

Naturalists travelling abroad are compelled to forgo the collection of individuals exceeding a certain size (except in the form of skins), solely because their preservation by ordinary methods (alcohol or formalin) necessitates the use of containers so large that their transport is quite impracticable.

There is, however, an extremely simple and quite inexpensive method of preserving animals, both large and small, and in particular fishes: this is by the use of sodium chloride or sea salt. I speak with some knowledge on this subject, as I have used the method myself on many occasions.

All that is necessary is to place the animal in a basin or dish, or preferably on a board or something of a like nature, and to cover it with a heap of salt, being careful to introduce as much of the salt as possible into the mouth and gills, as well as into the abdominal cavity through an incision previously made in one side of the body. The effect of the salt, of course, is to absorb the fluids from the organism. After some hours, that is to say, on the next day at the latest, the specimen should be turned over, drained, and the diluted salt replaced by fresh.

If the animal is of small or moderate size no further treatment is usually required, but if of considerable volume it may be necessary to repeat the operation several times, care being taken to turn the body over each time. Naturally, the hygrometric state of the surrounding atmosphere will tend to accelerate or retard the process as the case may be.

The desiccation of the specimen must be made as complete as possible, since, of course, the sodium chloride does not fix the tissues, and its preserving powers depend entirely upon its strong hydrophilism, the organic tissues treated by the salt being dehydrated and at the same time rendered unsuitable for the proliferation of destructive organisms such as bacteria, moulds, etc.

Thus, it is absolutely indispensable, especially in warm and humid climates, to obtain this dehydration as rapidly as possible, the animal being, in fact, converted into a 'stock-fish', which can be readily packed in any sort of box or crate, with no other packing than the salt itself.

By using this method I have been able to obtain very large specimens of fishes (for example, *Psettodes belcheri* Bennett, a flatfish from the north-west coasts of Africa, and enormous heads of halibut from Newfoundland), which would have been extremely difficult, if not impossible, to procure otherwise.

When the specimen reaches the museum or laboratory it should be soaked in fresh water for just long enough for it to resume its natural form; after this, it can be finally immersed in alcohol or formalin. The complete elimination of the salt is quite unnecessary, since its presence does not harm the final preservation.

I have never experimented myself with a mixture of sodium chloride and sodium sulphate, although I understand that this has given excellent results.

Clearly, this method of salting does not represent the ideal treatment for histological examination, but I can assure you that, not only the external morphology, but even the macroscopic anatomy, is perfectly clear; external characters, bones, viscera, muscles and nerves can all be easily studied. Obviously, the same cannot be said with regard to the blood-vessels or the brain, since special treatment is usually required before undertaking research on these organs.

I do not pretend that the external shape of a salted fish will always compare favourably with that of one which has been placed while fresh in alcohol or formalin. The colours are altered; frequently the scales are displaced. Admittedly the salt is only a makeshift, but how very much better than putrefaction and complete ruin?

I have dealt only with fishes, but there is nothing to prevent the use of salt for the preservation of any kind of vertebrate, provided that such necessary precautions as cutting open the peritoneum and the stomach, etc., are taken.

---

SEVENTY YEARS AGO

Nature, vol. 1, March 10, 1870

Science Education in Germany

Prof. H. E. (afterwards Sir Henry) Roscoe, F.R.S., contributed a second article on this subject. The earlier article, dealing with the universities, appeared in Nature of December 9, 1869; the present article deals with the "Polytechnic Schools".

"The 'Polytechnicum' is an institution peculiar to Modern Germany. It has for its object the teaching of all branches of the sciences of experiment and observation, not only in their principles, but in their applications to the industrial arts; these applications not being merely treated as illustrations of science, but regarded as the main subjects for instruction, for the sake of the understanding of which systematic courses on theoretic science are given."

The article points out that the polytechnics are quite independent of the science departments of the universities, although both are State institutions and there are often working arrangements between them. The professors rank somewhat below those of the universities. Entrance is normally at seventeen years of age, that is, one year earlier than to the universities.

The continued separation of the universities from the polytechnics is harmful in that it encourages the tendency in the polytechnics "to neglect the *educational* aspects of science in considering its practical applications".

A Probable Cause of Malaria

J. Gagliardi, writing under this title, refers to the work of Count Castracane on diatoms, described before the Academy of the Lincei. In this work, according to Gagliardi, he discovered that "nothing is so fatal to the life of marine or even brackish water diatoms as a sprinkling of pure fresh water. . . . From this fact he comes to the very probable conclusion that the sudden dying away of myriads of diatoms, besides, perhaps, myriads of other living creatures, during the rainy season might be, if not the only, at least one of the most efficient causes of *malaria*".

Natural Science Schools at Rugby

An article appears, by the Rev. T. N. Hutchinson, on these new 'schools', which is accompanied by a plan and an engraving of a general view of the laboratory. The laboratory is 35 ft. × 22 ft., and intended to accommodate thirty boys. The benches are divided into compartments each of which includes a cupboard and two drawers, two shelves, two gas taps, sink and water supply. A room is provided for the lecturer, and the chemical lecture theatre seats fifty. The physics lecture theatre seats sixty.

M. Delauney is the new director of the Paris Observatory. [See also Nature, February 10, p. 235.]

Prof. Unger, of Vienna, a well-known botanist, whose death we reported last week, was, it is now stated, found murdered in his bed at Graz; and no trace of the murderer has as yet been discovered. A priest has taken this opportunity to assert from the pulpit at Cilly, Styria, that the body of the late philosopher had probably been destroyed by the devil himself, who had just claims upon his soul!

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

A Mistress of Method for the Manchester Training College of Domestic Economy—The Director of Education, Education Offices, Deansgate, Manchester 3 (March 15).

Lecturer in Metallurgy in the Technical College, Bradford—The Director of Education, Town Hall, Bradford (March 16).

Headmaster of the Skipton School of Art and the Skipton Technical Institute—The Secretary to the Managers, School of Science and Art, Skipton, Yorks (March 18).

Waterworks Engineer and Manager—The Town Clerk, Municipal Buildings, Poole (March 20).

Director of Education—The Director of Education, Education Department, Newarke Street, Leicester (March 27).

Director of the Geological Survey—The Secretary, Civil Service Commission, 45 Upper O'Connell Street, Dublin (April 12).

Assistants III for duty on Resident Technical Officer Staffs at Aircraft Construction Works—The Under-Secretary of State, Air Ministry (B.127), Department ZA, Harrogate, Yorks (quoting B.381).

THE PLANNING OF RESEARCH

SOME time ago, Lord Chatfield gave a comprehensive account in the House of Lords, in reply to a question by Lord Strabolgi, of the organization of scientific knowledge and personnel in Great Britain in the prosecution of the country's war effort (NATURE, January 27, p. 134). Although speed of decision and action is vital in these days, it is perhaps as well that a fundamental question such as this should now be reviewed after an interval for reflection.

Broadly speaking, Lord Chatfield contended that the scientific talent of Great Britain is already mobilized to the best advantage. He pointed out that close contact exists between the civil directors of scientific research in the three Services, and urged that the professional ties of scientific workers who may be members of different departments would prevent departmentalism and facilitate the exchange of ideas. Lord Chatfield also laid special stress on the value of an annual review of the research work in progress in the research departments of the three Services. Similarly, pointing out that there is no central organization or clearing house for research between the three fighting Services, he considered that the existing organization is adequate to ensure that an invention gets into the hands of the appropriate expert as quickly as possible and that central organization might impose delay.

Satisfactory as this reply may be in many respects, it does not really deal with the fundamental problems which are agitating the minds of scientific workers at the present time, and indeed on some points of detail it is possible to regard Lord Chatfield as too optimistic. The demands of secrecy imposed by war-time are a serious if inevitable obstacle to the exchange of ideas, at least beyond a certain stage of development—possibly the most important of all from the point of view of practice. Moreover, there has already been a considerable curtailment of scientific meetings, which might well be rectified.

Lord Chatfield's reference to the annual review of Service research work and the dropping of long-range investigations which are not yielding immediate results, however advisable from a Service point of view particularly during war-time, touches on the first of the two major problems causing concern to scientific workers to-day. Already some science departments at the universities have adapted their research programmes in part to short-term problems which may soon be of urgent importance. In others, research has been interrupted or curtailed by transfer of staff or by requirements of the Services. In such circumstances, the problems of co-ordination between the various applied sciences and the integration of fundamental and applied research as a whole assume even greater importance. The progress of science and the needs of the present situation are daily widening the sphere of what must be regarded as practical research beyond the limits of present provisions.

Accordingly, it is being asked whether the existing structure and machinery of research are adequate to serve the needs of the country, whether in time of peace or in war. Secondly, the place and function of the universities, not merely in relation to the organization or prosecution of research, but also to the national life, are the subject of equally anxious discussion. The two questions are interlocked in numerous ways: the relation between the teaching functions and research activities of the universities; the endowment of long-range research; questions of professional training and training for leadership or citizenship, are all involved and in urgent need of attention.

To deal adequately with such major questions as these within the limits of a single article would be impossible, and for the moment our concern is chiefly with the adequacy of the present structure of research. This has been the subject of criticism in recent years, notably in the Memorandum on the Finance of Research prepared by the Parliamentary Science Committee, and by Prof. J. D. Bernal in "The Social Function of Science". More recently, it has been discussed by Dr. Bernard Lovell in "Science and Civilization" with the view of provoking further discussion.

A preliminary analysis of academic research was presented at the Dundee meeting of the British Association in September last, and this analysis has been included in a recent broadsheet, "The Role of Research", issued by P E P (Political and Economic Planning). Even this preliminary survey makes clear the extreme difficulty of estimating with any accuracy the man-power engaged in academic research. Research staff on a full-time basis is not readily distinguished from staff engaged in part in lecturing or demonstrating, and great difficulties are also encountered even in defining a university institution, especially in the spheres of technology and technical training.

An outstanding feature of this preliminary survey is its revelation of the insignificant provision made in universities in Great Britain for the study of descriptive and theoretical sociology. While the group of social studies as a whole is well represented, the bulk both of its staff and students is found in departments of history, economics or law; contemporary social relations are scarcely studied from any point of view wider than that of economics. An excess in the proportion of advanced students over the percentage figure for the staff is most marked in departments of chemistry, but also appears in education, history and economics. The serious strain imposed on the teaching staffs by this disproportion cannot be without effect on their research time.

This preliminary survey thus supports the numerous pleas which have been voiced for some re-orientation of research effort between the physical sciences and the social and biological sciences. The unbalanced distribution of research resources even in war-time is likely to be fraught with serious consequences, to some of which attention has been directed from the economic side. The difficulties encountered in evacuation schemes have already indicated the need for more objective social research, and the success of rationing and other measures imposed by the national emergency may increasingly depend on accurate scientific knowledge of social needs and problems.

On this ground alone, therefore, inquiry into the present structure of research appears to be justified. It is not disputed, as Lord Chatfield urged, and as Sir Robert Robertson observed when the B.A. report was presented at Dundee, that effective machinery of co-operation exists in the Advisory Council for Scientific and Industrial Research, the Agricultural Research Council and the Medical Research Council. The improvement in this respect in the last twenty years is entirely satisfactory. What is unsatisfactory, however, is the inadequacy of the resources available for such bodies, and their limitation to advisory functions as distinct from the initiation of policy. Dr. Lovell contrasts, for example, the £195,000 received by the Medical Research Council for research with the £3,000,000 spent every year on advertising patent medicines and the annual turnover of £20,000,000 from their sale.

A second unsatisfactory feature of the situation is the absence of a co-ordinating authority able or competent to divert available expenditure or resources from one major field to another as the need is demonstrated. Despite the established value of long-range research in providing the basis of technical advance, such fundamental research remains in the most precarious position of all. Its efficiency depends on continuity, and yet it is probably more liable to abrupt termination or interruption than any other type. The importance of provision for continuity, which is the only satisfactory guarantee that half-completed work may not be utterly wasted, can scarcely be overstressed. Something much more effective than the existing methods of co-operation is essential to initiate the rationalization necessary to bring the whole cycle of research into a comprehensive and ordered scheme.

Failure to realize the basic interdependence of research—that research, whether prosecuted in the universities, in industry or in Government departments, is not distinct but a part of the same mechanism—not only threatens to handicap the solution of problems of reconstruction in time of peace, but is also a real danger to the efficiency of our war-effort. Already it is clear that many of our difficulties in dealing with the problems of adjustment from a peace-time to a war-time economy are due to our past neglect of research in the social and biological sciences. Many aspects of administration and government, the directive part of man and most aspects of human values are largely untouched by scientific investigation.

It is this position which makes Lord Chatfield's account of consultation and contact between the different Service departments less reassuring than it might otherwise be. Even if there were a co-ordinating authority competent to sort out long-range investigations, discontinued as a result of the annual review of the Service departments, and ensure their continuity where desirable, we could not regard the position as satisfactory while there appears to be no means for initiating those researches on the social side, which may well have a decisive influence on national morale. It has to be remembered in this connexion that there is already a marked tendency in industry, for example, to ignore the lessons of the War of 1914–18 and the experience of the Industrial Health Research Board, as was pointed out at a recent symposium of the Industrial Section of the British Psychological Society (see NATURE, February 3, 1940, p. 174).

In comparison with the position during the War of 1914–18, the organization of research, of course, represents an immense advance. The Advisory Council of the Department of Scientific and Industrial Research is very clearly alive to the danger of interrupting research, and has already deprecated any hasty reduction of work by the research associations without careful consideration of its ultimate effect on the welfare of the industries they serve. While wise adjustment of research programmes may enable the various associations to anticipate and deal with problems requiring immediate solution, the Advisory Council is anxious that fundamental investigations should be continued so far as possible. The Government, moreover, is to continue its pre-War rate of grants.

Satisfactory as this position may be, the crux of the situation is in the universities, where by far the greater proportion of fundamental research is prosecuted. Apart from the ill-defined relation between teaching and research, there is considerable waste of time on routine constructional work owing to the absence of technical assistants and mechanics. This waste has not been recognized by the authorities, and in war-time the demands of munition work and other forms of national service are likely to accentuate the evil by increasing the already acute shortage of qualified assistants.

The fundamental problem of university research is, however, that of widening the front of scientific advance, and while preserving the independence of the research worker and avoiding any regimentation, of securing that the resources available are adequately distributed over the whole field of science, and particularly those branches of knowledge where fundamental advance is most urgently demanded to meet the needs of the nation. Some strategy of scientific advance is imperative if resources are to be maintained unimpaired under peace-time conditions; if they are attenuated in war, it may make all the difference between victory and defeat.

The first steps to some such co-ordinated strategy must come from within the ranks of scientific men themselves. It is a matter which concerns all classes of scientific workers, however effectively some of the stronger groups, such as the chemists, might contribute through their professional organizations to the removal of particular handicaps on efficiency. Through the Royal Society or the new Division for the Social and International Relations of Science of the British Association, something of a plan of advance should be elaborated, taking account of existing gaps in the front of science, the border-line territories which are apt to be neglected and the manifold needs of a society at war and of the reconstruction to follow. Only with such a broad plan as basis will it be possible to compute the effort required, and the extent to which existing resources must be supplemented or diverted.

Given such a plan, some type of executive authority and scientific General Staff will be required to carry it out. The nucleus should not be hard to find in the Advisory Council on Scientific Research and Technical Development and existing organizations. Here, however, as on the economic front, the primary need is for vision and drive. It is only when scientific workers themselves realize the immense possibilities in their hands that we can hope for the elaboration and execution of that plan. From them must come the pressure on their individual societies and associations for the formulation of a common policy, and the resolute attack on all forms of inefficiency and waste in scientific research, and on obstacles to its development. On them individually, too, must rest a large share of the responsibility for making both the Government and the public realize the value of the contribution which science could make and the means by which that effort should be organized and directed.

PRINCIPLES IN PHYSICAL SCIENCE AND FREE WILL

The Philosophy of Physical Science
(Tarner Lectures, 1938.) By Sir Arthur Eddington. Pp. ix + 230. (Cambridge: At the University Press, 1939.) 8*s*. 6*d*. net.

THE following process is recurrent in physical science. A certain amount of special knowledge, empirically accumulated and assorted, is tentatively cast into a comprehensive theoretical aspect. The theory, after having been gradually corrected by further experiments and after having created several new appropriate definitions, tends to acquire an unforeseen general validity. But, strangely enough, at the same time, when it has become an inalienable requisite for the orientation of all future experimental and theoretical research, the knowledge which its propositions are supposed to convey turns out to be more and more tautological.

Withdrawn from the action of forces, a body moves uniformly in a straight line; with a force acting on the body, there is a rate of increase of speed, proportional to the force. These laws were originally abstracted from empirical findings. Subsequent generalization turned them into the tautological assertion that a body moves uniformly in a straight line unless it does not, in which latter case the force is to be judged by the body's acceleration. An appropriate definition points out the relevant notion by giving it a name of its own (force). What is left of the law is the important hint: In mechanical problems, pray, pay primary attention to the *second* derivatives—it is *they* which matter.

The example is old-fashioned and would need re-modelling to-day, but it is simple and sufficiently illustrative. The three laws of thermodynamics (principle of energy, principle of entropy, Nernst's theorem) have acquired almost a similar standing. Though they are not tautological, it would seem a rather hypocritical broadmindedness to maintain that they are empirical regularities only and could be contradicted by experiment at any time. I should not venture to oppose a view which in these and similar cases (for example, that of the special theory of relativity) went so far to the other extreme as to hold that the content of the theory had been switched over—intentionally or inadvertently—from empirical regularities to essential ingredients of our method of attack on problems of physical science, and had thereby been both deprived of the benefit and withdrawn from the danger of being checked by experiment.

The book under review goes further than that. It is said that recent advance in physical science has made us aware of the epistemological method, which consists in "examining the sensory and intellectual equipment used in observation" (p.18), and allows us to reach at least some of the fundamental laws of physics with "a security which is denied to those that can only be reached empirically" (p. 19). After the "replacement of physical hypotheses by epistemological principles" (p. 45), those laws turn out to be "compulsory and universal" (p. 45). This is "the equipment to put theoretical physics on a surer footing than it formerly aspired to" (p. 21).

Both views—that which I said I would not venture to oppose and Eddington's—claim the subjective character of certain fundamental laws. The peculiar brand of Eddington's subjectivism is best revealed by his incidental criticism of H. Poincaré's famous statement concerning geometry (p. 72). According to Poincaré, we can never decide by experiment which geometry is the right one, because any one will do, provided that the laws of physics to go with it are appropriately chosen. But they are functions of the geometry. We naturally, yet arbitrarily, decide for that geometry which gives our description of physical Nature the simplest form. It is thus not the "true" one, but the *comfortable* one, says Poincaré. If Eddington pointed out that, according to present knowledge, spherical geometry (with slight deviations for the local gravitational fields) was the only one not to entail an intolerable amount of inconvenience, I should agree. But, drawing on a quotation from "Science et Hypothèse" which, I confess, is a little daring and slightly over-stated, he declares that experiment, theory and epistemological research have definitely set an end to the happy-go-lucky times when we could allow a pure mathematician his extravagant dream of liberty to choose which geometry he liked.

I am probably not the only one who has always looked upon Poincaré's thesis as one of the most important revelations—and a genuinely relativistic one, at that. I consider it to be irrefutable and claim the same liberty of choice with respect to all those fundamental laws of physics (or constituents or features thereof) to which a purely subjective standing is duly attributed at any stage of the development of science. But the ease and simplicity of our description of Nature (or, if that is preferred, of our comprehensive report on our physical knowledge) is a function of our choice, showing usually a tremendous, almost selective, maximum for a particular choice. This is what determines the latter. As for the rest of the laws, I am not keen on calling them objective and anchoring them in an "objectively existing Universe" (which Eddington rejects). The *external world*, which he willingly grants (p. 209, p. 216), suffices for that purpose.

Another question of primary importance has received much attention, ever since the indeterminist view of quantum mechanics made its appearance in physics. Does the gap left in the predictability of events leave room for conscious volition to have its share in determining them? I cannot help being bewildered by the author's comments on this question. In the first place, he finds the limits of uncertainty left by Heisenberg's principle somewhat narrow for volition to get its proper share. He therefore pulls them down, claiming a *correlated behaviour* of the particles in, at least, some parts of brain-matter (p. 183). But Heisenberg's principle is supposed to be of epistemological origin (p. 99, p. 183) and therefore (p. 181) to hold also for brain-matter! Secondly, any kind of correlated behaviour or "demonic influence", whether outside the Heisenberg limits or within them, is bound to violate the second law of thermodynamics. If that is the meaning (and I am afraid it is), then the soothing statement (p. 181) about the "obedience of brain matter to the fundamental laws of physics which, being of epistemological origin, are compulsory for all matter", is grievously impoverished by the absence of a comma before "which". This is not the place to dwell upon my personal view, in which the alleged antithesis between rigid causality and free will is an illusion and the attempts to bridge it go so far astray as an attempt to explain the behaviour of an atom by its hunger or joy. But quite apart from this, say, prejudice of mine, I have always failed to appreciate the satisfaction felt about the gap which quantum mechanics is supposed to have opened for the purpose. The suggestion might be worth considering, if it succeeded without any exceptional law altogether. But there is actually no gap for volition to creep in, unless we are prepared, in certain exceptional areas, to sacrifice the Second Law. I do not consider that to be better or worse than it would have been thirty years ago, to abolish determinism in those areas.

There is still one question which I cannot repress: What is the source of the knowledge (p. 218) that "matter is normally unassociated with consciousness"? That a being organized much the same way as myself has likewise consciousness is a natural inference. But can it be inverted? Is not a certain likeness in organization the necessary condition for becoming aware of the fact? How should a galaxy, if it were associated with consciousness, and a human being communicate? The idea is that of G. Th. Fechner.

By not repressing my criticism of an author whom I deeply admire, I hope that I have, at least, conveyed to the reader how fascinating and stirring this book is from the first to the last page. There are many chapters upon which I could not comment at all—perhaps the most interesting ones. No man of science should miss reading the book. But with a work of Eddington's these are truisms. I propose to take a phrase on p. 113 as a motto for the whole—in spite of the author, who would certainly disagree. It reads: "I have been acting as an advocate for an extreme view, presuming that your natural prejudices are all the other way."

E. Schrödinger.

TALKS ABOUT GARDENING

Science Lends a Hand in the Garden

By Sir Frederick Keeble. Pp. xi+307. (London: Putnam and Co., Ltd., 1939.) 10*s*. 6*d*. net.

The leading articles in the weekly publication, the *Gardeners' Chronicle*, are frequently concerned with the application of recent scientific investigations to garden practice. A considerable number of these articles written by Sir Frederick Keeble are now brought together, carefully arranged and published in book form. The author states in the preface: "This book contains what are really talks about gardening——" "They don't set out to teach, but only to let gardeners know what people are gradually learning about plants and the soil they live in." The author certainly succeeds "In writing these things in the simplest possible way".

It is not feasible to direct attention to all the topics discussed; mention of but few must here suffice. The earlier chapters concern soil factors, fertilizers, and the humus content of soil and composts; a chapter is devoted to fruit, in which rootstocks, ripening and storage are discussed. Various environmental factors influencing the growth of garden plants are considered, and several pages are devoted to newly reported diseases and remedial measures; the production of new varieties by plant-breeding forms the subject matter of another chapter.

Many worthy garden plants are mentioned and there are hints on their cultivation and methods of pruning, together with brief descriptions of the peculiarities of some of these plants. The author has briefly drawn upon his wide experience in recommending some of the best shrubs.

The text reads easily; the charming literary style of Sir Frederick may gently persuade or beguile the reader to attempt more than "A chapter at a time" as is modestly suggested in the preface. When bringing to the reader's notice the results of recent research the author facilitates reference to the original work but does not quote fully 'chapter and verse'. There is an adequate index, but the book is without illustrations. A number of good photographs will always attract the keen amateur and general reader.

This book forms a general introduction to, and a brief review of, the progress made in applied botany (other than systematic studies), and is suitable for the general reader. It should interest botanists generally as it indicates many attractive problems yet to be solved. Few gardeners will fail to grasp the hand that science lends, and many amateurs will be grateful for the introduction so effected.

THE FUNCTION OF THE ADRENAL CORTEX

Die Funktion der Nebennierenrinde
Von Prof. F. Verzár. Pp. 266 + 4 plates. (Basel: Benno Schwabe und Co., 1939.) 25 Schw. francs.

VERZÁR, from whose laboratory have come many contributions to the knowledge of the function of the adrenal cortex, has published an extremely interesting monograph on this subject. A bibliography of more than 1,500 references is included, about 1,100 of which are from the last ten, and about 550 from the last three years. This illustrates the rapid progress recently made in the knowledge of this organ of which, as Verzár states, until a few years ago little was known except the fact that it is indispensable to life. Verzár gives a vivid impression of the rapidity of this progress when he describes, in the chapter on the chemistry of the cortical hormone, how the important contributions from three laboratories, from that of Kendall in Rochester, of Reichstein in Zurich and of Winterstein in New York, followed one another sometimes at less than monthly intervals.

In the early chapters the different methods are reviewed for removing the adrenals and for assaying the cortical hormone, and the history of its chemistry and identification is told. The last third of the book is concerned mainly with the conditions of hypertrophy and atrophy of the cortex, with its relation to other endocrine organs and with clinical observations. The material is well reviewed, and new suggestions are put forward. Some of the disturbances in the carbohydrate, fat, and ketone metabolism which develop after removal of the pituitary body can be restored to a great extent by cortin and may be regarded as signs of insufficiency of the adrenal cortex, which becomes atrophic after the operation. A detailed account is given of the morphological, chemical and experimental basis for the theory of production of sex hormones from the adrenal cortex under normal and abnormal conditions.

The main interest, however, centres around those chapters (vi to xv and xxii) dealing with cortical insufficiency and the functions of the cortical hormone. According to Verzár, it acts on the cell metabolism, enabling the processes of phosphorylation to take place in the cells. Lack of the hormone leads to impairment of phosphorylation in the organism, and the symptomatology of cortical insufficiency may be regarded mainly as the direct or indirect outcome of this disturbance. The starting point for this conception was a comparison of cortical insufficiency with iodo-acetic acid poisoning in which phosphorylation is impaired. Verzár was struck by the similarity existing between the two conditions, and the comparison has been the guide in the development of his theory.

The most conspicuous sign of cortical insufficiency is muscular weakness. The contraction curves from adynamic muscles resemble those obtained from muscles poisoned with iodo-acetic acid. According to Verzár, absence of cortical hormone, like iodo-acetic acid poisoning, affects the chemical processes of restitution in muscle which are associated with lactic acid formation. Numerous experiments are quoted showing the disturbance in lactic acid formation and in the whole carbohydrate metabolism. In adrenalectomized rats the disappearance of injected lactic acid is slowed down, the oxygen consumption and the carbon dioxide output are only slightly increased during exercise, which is attributed to impairment of lactic acid formation, there is only a slight increase in the lactic acid concentration of indirectly stimulated muscles, formation of glycogen is impaired, liver and muscle glycogen are low and the blood sugar, therefore, has a tendency to fall during exercise.

Verzár's analysis of these metabolic changes started by studying the absorption of sugars from the intestine. In adrenalectomized rats as well as after iodo-acetic acid poisoning, the selective absorption of glucose and galactose was found to be inhibited. The selective absorption is attributed to phosphorylation of these sugars in the intestinal epithelium, and the cortical hormone is to bring about this reaction not only in the intestinal epithelium but also generally in all cells. In this way the changes in the carbohydrate metabolism during cortical insufficiency are explained. The theory is further made responsible for explaining changes in salt and water metabolism. Phosphorylation is also thought to be the key to the changes in fat metabolism. In adrenalectomized animals and in iodo-acetic acid poisoning the development of fatty livers after different forms of treatment is prevented and the fat absorption from the intestine is inhibited. This is explained by inhibition of fat synthesis in the epithelium due to impairment of phosphorylation, in this case of the phosphatides.

Another interesting outlook is the relation of the action of the cortical hormone to enzymes and vitamins, particularly those of the B group. The respiratory enzyme of Warburg contains as prosthetic group vitamin B_2 (lactoflavin or riboflavin), which is phosphorylated and linked to the protein. According to Verzár the cortical hormone enables the phosphorylation to take place, and lack of cortin results in the inability of phosphorylating riboflavin. In adrenalectomized rats and in iodo-acetic acid poisoning the growth ceased; it could be restored by flavin phosphoric acid but not by riboflavin. In further experiments on adrenalectomized animals the ratio between free and bound lactoflavin was found to be reduced from 1 : 10 to 1 : 1. It is assumed that the phosphorylation of vitamin B_1 to cocarboxylase is also impaired during cortical insufficiency. Recent experiments, however, of Ochoa and Rossiter (*J. Physiol.*, 97, 1P.) "offer no evidence for the theory that the adrenal cortical hormone is necessary for the phosphorylation of vitamin B_1".

In the concluding chapter a diagrammatic representation is given of the changes occurring in cortical insufficiency to illustrate how they all, those of carbohydrate, fat, sodium, potassium and water metabolism, may be traced back to impairment of the one basal factor of cellular metabolism, phosphorylation.

We may be grateful to Verzár for having given us such a clear and detailed account of his attractive theory, the ultimate value of which remains to be decided by future experiments. His results have to be confirmed and new experiments carried out before the theory will be generally accepted.

W. FELDBERG.

ECONOMIC ENTOMOLOGY

Destructive and Useful Insects

Their Habits and Control. By Prof. C. L. Metcalf and W. P. Flint. (McGraw-Hill Publications in the Agricultural Sciences.) Second edition. Pp. xvi+981. (New York and London: McGraw-Hill Book Co., Inc., 1939.) 50*s*.

THIS second edition is a comprehensive work intended for the student of entomology as well as for the practical man in the agricultural or veterinary field. It is conveniently arranged to this end.

The first third of the book includes a generalized treatment of the importance of insects to man together with a simplified account of the morphology, physiology and development of these animals. The physiology of insects has been described as the handmaid of economic entomology, and one would have preferred this part to have been enlarged and brought into closer reference with the later economic sections. In these pages, too, is an account of the principles of insect control with the stress on practical rather than academic aspects.

The rest of the volume is concerned with accounts of some 370 pests—agricultural, veterinary and medical—and the practical man to whom these pages will appeal is provided with helpful keys and descriptions for their identification.

New features of value in this edition are the cross-references given to those insects whose damage lies in more directions than one, the keys for the identification of young as well as adult stages and the additional matter relating to modern aspects of chemical control.

The book contains a wealth of valuable practical information. Omissions are, however, inevitable. For example, the Aphidæ are credited with doing no more damage than that caused by robbing the host plants of fluid, and no mention is made of the conjunctivitis fly, *Hippelates pusio* of California, which is within the area covered by this book.

Following a discussion on page 161 on the need for scientific names instead of 'nicknames', it is remarkable that each species is recorded under its 'nickname' in bold type, the scientific name being relegated to a footnote and in some cases omitted altogether, as on p. 483.

The book is copiously illustrated by clear figures, though some of these have suffered in reproduction. It is carefully indexed and well printed and deserves a good reception, especially from all students of entomology in the United States and southern Canada, the area which it is intended to serve.

L. E.

MOLECULAR STRUCTURE AND RAMAN SPECTROSCOPY

The Raman Effect and its Chemical Applications
By James H. Hibben. With a Theoretical Discussion by James H. Hibben and Prof. Edward Teller. (American Chemical Society, Monograph Series, No. 80.) Pp. 544. (New York: Reinhold Publishing Corporation; London: Chapman and Hall, Ltd., 1939.) 66*s.* net.

MODERN students of molecular structure have before them the double objective of the determination of the positions and mobilities of the atoms in a molecule, or, in other words, the equilibrium atomic configuration and the intramolecular force field; and their ideal is to achieve a complete and quantitative description of these complementary features of structure. Two types of method of outstanding value are available for the quantitative study of atomic configuration, namely, a group of interferometric methods, either with electrons or X-rays, and a group of spectroscopic methods, which may be summarized under the name long-wave spectroscopy. One method only is available for the complementary study of intramolecular force fields, namely, the method of long-wave spectroscopy.

In long-wave spectroscopy the immediate object is to observe rotational and vibrational frequencies: the former are parameters for atomic configuration, the latter for both atomic configuration and intramolecular forces. Prior to 1928 the only direct method of observing such frequencies was by the study of absorption in the infra-red region of the spectrum, but with the recognition of the Raman effect, that is, that a rotating or vibrating molecule, when scattering light, may change its frequency by the frequency of the rotation or vibration, a second direct method became available. One advantage of the new method, its much simpler technique, was immediately appreciated, and observations of frequencies began to be added to the records at a rate never achieved by the method of infra-red spectroscopy.

As the theory of light scattering became better understood, it appeared that a second, and still more important, factor contributed to the value of Raman spectroscopy. For many molecules certain vibrations exist which cannot in principle record their fundamental frequencies in the infra-red spectrum. It is usually true for the same molecules that certain of their vibrations will not exhibit their fundamental frequencies in the Raman spectrum. However, the rules which govern the exclusion of frequencies from the two spectra are different, so that, by examination of both spectra, it may be possible to obtain a complete set of molecular vibration frequencies; and it will almost always be possible to obtain a more complete set than would have resulted from the application of either method separately: the two methods are complementary.

Dr. Hibben has now produced a book which may be regarded as a complete manual of Raman spectroscopy, alike from the points of view of experiment and theory. The work opens with a description of apparatus and a summary of all the information necessary to anyone who, without previous experience, wishes to make measurements. There follow four chapters, written in collaboration with Dr. E. Teller, on the theory of molecular vibrations and rotations, the theory of infra-red and of Raman spectra, of the vibrations and force systems characterizing molecules of particular types, and of factors such as isotopic substitution which modify spectra in predictable ways. This section is written with great clarity, and is, indeed, a striking example of the achievement of simplicity without loss of precision in a mathematico-physical subject. A good example of this is the product rule, which is derived and fully explained on a single page with the aid of only three formulæ. In the chapter on the vibrations of particular molecules, an effort seems to have been made to include all the formulæ likely to be useful to anyone wishing to calculate the force systems of simple molecules from the observed frequencies.

The chapter on isotopic substitution brings out the enormous advantage which this device confers on vibrational spectroscopy. Before 1935 there was no general method of passing rigorously from observations (frequencies) to ultimate conclusions (force fields) by the route

$$\text{Frequencies}\rightarrow\begin{cases}\text{Equilibrium configuration.}\\[6pt] \left.\begin{array}{l}\text{Vibration forms}\\ \text{(assigned to the}\\ \text{frequencies).}\end{array}\right\}\rightarrow\text{Force system,}\end{cases}$$

because, in the first place, there was no definite, quantitative test to confirm a configuration, and an assignment of its vibration forms, assumed as the interpretation of an observed set of frequencies; and, because, secondly, with a correct molecular model and a correct assignment, the number of frequencies was, for all but the very simplest molecules, smaller than the number of parameters needed to specify the force field. The method of isotopic substitution overcomes both difficulties, because the product rule, applied to the frequencies of isotopically related molecules, provides a test for any assumed model and any assignment of its vibration forms; and because by measuring the frequencies of a sufficient number of isotopically related molecules it is possible, in principle at least, to obtain a sufficient number of frequencies fully to specify the common force system.

The last three quarters of the book contain an exhaustive summary of the observations of Raman spectra over the whole field of organic and inorganic chemistry. Special points of physical or chemical significance are discussed in passing, and the text is illustrated with many interesting microphotometric traces of Raman spectra. These brief discussions will doubtless stimulate much research; indeed it is impossible to read five pages anywhere in this part of the book without wishing to investigate some question. A highly valuable feature is the bibliography and index of compounds, which together constitute a complete guide to the literature of the Raman effect. Heavy labour must have been expended on this compilation, but, writing so complete a work, the author has rendered a signal service to science, and to all interested in the subject of molecular vibrations.

C. K. Ingold.

HISTORY OF LIGHTING APPLIANCES

The Story of the Lamp (and the Candle)
By F. W. Robins. Pp. xiv + 156 + 28 plates. (London, New York and Toronto: Oxford University Press, 1939.) 15*s*. net.

It is surprising that such a commonplace subject as that of lighting appliances should be so poorly documented. There are plenty of references for those who have the time to find them, and there is always Hough's scholarly catalogue published some years ago as *Smithsonian Bulletin* No. 141. For the mechanical era, which title applies only to the last hundred years or so, there is a comprehensive account of earlier devices entitled "Chemical Technology", volumes 2 and 3, by Groves and Thorpe and published in 1895 by J. and A. Churchill, while for the present century information is not difficult to obtain.

In the volume under review, Mr. Robins has made an attempt to provide a treatise in which the subject shall be dealt with in some detail, and at the same time provide interesting reading as a narrative. The attempt has not been unsuccessful, although there are certain limitations such as the condensation of the final century, when illuminating power rose steeply, to a sketchy account of ten pages.

In the 5,000 years preceding Argand's invention of his doubly aerated burner, there was little improvement over the illuminating power of the lamps devised in Sumerian times; but of lamps, candles and torches there were so many forms and independent origins that it has taken a considerable degree of skill to weld the history into a readable form.

The author, in obtaining the material for his book, has acquired a noteworthy private collection, of which some five hundred items are illustrated in the twenty-seven plates. Errors of fact are few, but occasionally there is evidence of the inevitable pitfalls of over-compression normal to the presentation of such a wide subject. Thus on page 21, the author boldly refers to the first American discovery of petroleum as having occurred in the year 1859, when the Pennsylvania wells were opened, whereas d'Allion, writing in 1629, recorded its use medicinally by the Indians, and there were many other records in the intervening years.

In the "Prologue" the author expresses the hope that the book will be a substantial nucleus to which additions may be made, and in particular there is a reference to the ethnological significance of lighting developments which appears not fully to have been explored.

It is to be hoped that this treatise may provide the stimulus for a fuller investigation of the influence of the lamp and candle on contemporary developments, and that the work which Mr. Robins has begun will lead to extensive research in a field which is at present most inadequately explored.

W. T. O'D.

HISTORY OF THE VACUUM FLASK*

BY SIR WILLIAM BRAGG, O.M, K.B.E., PRES. R.S.

FEW laboratory devices have achieved the popularity of the vacuum flask. Since Sir James Dewar designed it for the purpose of preventing his liquid air from rapid evaporation, the flask has become a household friend and an invaluable tool in the laboratory and the workshop. It is so very simple and yet so very efficient. Each of the ways by which heat can pass from place to place, by convection, by conduction and by radiation, is almost entirely blocked, with the result that everyone knows.

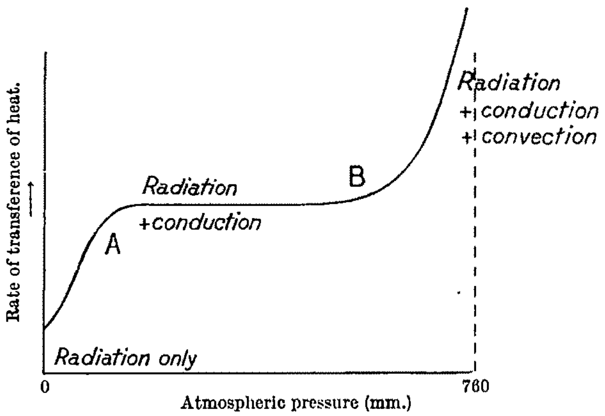

Fig. 1.

GENERAL FORM OF A CURVE SHOWING THE RELATION BETWEEN THE RATE OF TRANSFERENCE OF HEAT ACROSS AN AIR SPACE AND THE PRESSURE OF THE AIR.

Quite apart from the aptness of the design, the gradual discovery of the principles on which it is based makes a story of great interest. The pioneers in the study of heat believed that an examination of the methods by which heat is transferred would offer the best chances of discovering the nature of heat itself. Consequently their experiments were remarkable in themselves; and moreover, their interpretations of what they observed throw a curious light on the workings of their minds as they tried to establish one or other of the widely differing theories then held.

Thus Rumford in 1785 hung a thermometer by a thread in a closed vessel and set out to find whether or no heat was helped or hindered on its way to the thermometer by the air through which it must pass. He expected to find that removal of the air would hasten the transference of heat, because he believed that heat was associated with motion, and that the transference was effected by a wave motion in a medium which could not be evacuated. The air in his vessel would not on that theory be the actual carrier of the heat and might well be a hindrance. He formed a Torricellian vacuum in his vessel by first filling it with mercury, which was heated to drive off any attached air, and then draining it in the usual way. It then appeared that the transference was less rapid than when the vessel contained air at atmospheric pressure. This may not have been what he expected, but nevertheless it favoured his theory because it seemed to show that heat could cross a space void of air. As a matter of fact, there must have been enough air left to be important, but he could not have known that. His critics, whom we may take to be represented by Leslie—whose experiments will be described later—supposed that air was alone responsible for the transfer and refused to believe that heat could cross a vacuum.

As we know now, the relation between the flow of heat across any space and the pressure of the gas in that space can be represented by a curve of which the general form is shown in Fig. 1.

The positions of the bends at *A* and *B* and the dimensions of the curve depend on the form of the experimental vessel, the condition of its walls and the nature of the gas which it contains. If the emitting and the absorbing surfaces within a vessel are small compared with the dimensions of the vessel, convection will play a large part unless the pressure is small, and the bend at *B* will then be far to the left of the figure. If convection is not serious, a long level stretch from *B* to *A* will show that the conduction is independent of pressure—as Maxwell proved—until at *A* the free path of the molecules becomes comparable with the dimensions of the vessel. If evacuation passes this point, conduction rapidly ceases and radiation acts alone.

Rumford's vacuum was good enough to take him some way round the corner at *A*, but he could not have known how far he had yet to go. Air was still doing most of the work. He may perhaps have reduced the pressure to a tenth of a millimetre.

A little later (1798), Rumford carried out his famous experiment of the generation of heat during the boring of a cannon. About the same time he compared with great care the weight of a mass of water when hot and when cold and, finding no difference, placed the result to the credit of the 'motion' theory. The supporters of the theory that heat was a form of fluid were by no means impressed by all these arguments. Davy and Young supported him, but they were very much in the minority. Leslie was an energetic opponent. "In the infancy of science", wrote Leslie ("An Enquiry into the Nature of Heat", p. 139 (1804)), "heat was supposed to consist in certain intestine vibrations". He had not changed his mind when he wrote "Dissertation Fourth" prefixed to the seventh edition of the "Encyclopædia Britannica" (1830).

---

* Substance of lectures at the Royal Institution delivered on December 7 and 14.

Leslie supposed that light traversed space in material form and entered into some kind of combination with the matter of any body on which it fell; in that way heat was produced. Heat itself, as such, could not cross a vacuum. The transfer of heat across an air space was accomplished through the simultaneous agencies of air pulses and of air jets directed from the hot body. Herschel in 1800 showed that a thermometer when placed in the spectrum and also when placed well outside the red end of the spectrum showed the receipt of heat without the agency of light. It was then asserted that his experimental arrangements were at fault. "This bold hypothesis was for a time regarded with wonder and applause but the delicate observations of Berard soon demolished the fabric. The notion of dark rays of light which enveloped the science in mystery stands now therefore without any proof and is utterly discountenanced by sound philosophy" ("Dissertation Fourth", p. 636). Herschel's own interpretation of his experiment is very interesting. He supposed that there were two forms of radiation, one constituting light and the other heat, and that they overlapped. "Those who would have the rays of heat do also the office of light must be obliged to maintain the following arbitrary and revolting proposition: viz., that a set of rays conveying heat should all at once in a certain part of the spectrum begin to give a small degree of light" (*Phil. Trans. Roy. Soc.*, **90**, 508). If this attitude seems surprising to us, we may well remember that we are less inclined in these days to consider our natural senses to be the perfect overriding judges of natural effects. Herschel would think that light and eyes were made for each other, that the intensity of light in different parts of the spectrum both as sensation and as cause of sensation was what the eye could see there, and that it was "revolting" to suppose that there was something of the same nature as light which the eye could not see.

Since Rumford made these first experiments, a number of workers have examined the passage of heat across a gas-filled space, not with Rumford's purpose of discovering whether air is necessary, but as tests of theories connecting amounts of transference with difference of temperature. Dulong and Petit did not use a high vacuum: they speak of 2 mm. mercury as being usual (*Ann. Chim. Phys.*, **7**, 245; 1817), so that their evacuation cannot have taken them round the corner at *A*. In 1875 Kundt and Warburg (*Pogg. Ann.*, **156**, 177; 1875) carried the experiment to the limit. They had good pumps and they cooked their containing vessels so as to drive off gases adhering to the walls, a procedure which they found to be absolutely necessary. As they arrived at the same figure for the transference no matter whether air, hydrogen or carbon dioxide had been in their vessel before evacuation, the last traces of gas must have been gone before the measurements were made. The remaining transference must have been due to radiation alone: in their case it was of the order of the fourth or the fifth of the amount when the vessel was full of gas, but of course this figure has no absolute meaning since it depends on the conditions of the experiment.

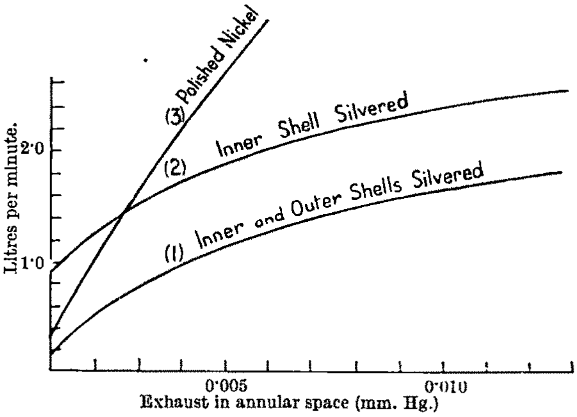

Fig. 2.

THIS FIGURE IS TAKEN FROM DEWAR'S PAPERS, VOL. 2, P. 1265. IT SHOWS THE RELATION BETWEEN THE AIR PRESSURE IN THE ANNULAR SPACE OF A VACUUM FLASK AND THE LEAKAGE OF HEAT MEASURED BY THE AMOUNT OF LIQUID AIR EVAPORATED FROM THE INNER VESSEL. THE AIR PRESSURE IS VERY LOW, SO THAT THE EFFECTS OF RADIATION ARE CLEARLY SHOWN.

When Dewar began to construct his vacuum vessels, he also found that the greatest care must be taken to remove the last traces of gas: very often the vessels had to be kept in the heated oven for many days.

The next feature of the vacuum flask to be considered is the silvering of the walls bordering on the evacuated space. In the early days, to which I have already referred, the connexion between the amount of radiation emitted or absorbed and the surface of the emitter or absorber was also a subject of interest, because, as already said, it might be expected to give information as to the nature of heat. Rumford and Leslie made experiments in this field, those of the latter being perhaps the best known. Their methods were similar, and their results also. Both used a 'thermoscope' resembling the earlier instrument which Leslie had made for his studies in hygrometry. Leslie's results were published in March 1804 in his "Inquiry into the Nature of Heat": Rumford's results were published in various places, some of them, for example, in the *Transactions of the Royal Society* in January 1804.

The two authors were probably unaware of each other's work and their publications may be considered to be simultaneous. Their interpretations were, of course, poles apart. Leslie supposed that metal surfaces reflected well, but emitted or absorbed badly because there was a layer of air in a special condition next all surfaces across which heat pulses could not pass, and that this was narrow in the case of non-metallic surfaces but wide in the case of metals unless the surface was roughened, in which case the peaks projected into the outer air. Rumford did not attempt such an intimate explanation, but merely recorded his results in terms of vibratory motion. He made one interesting mistake. He ascribed a definite frequency to each temperature, not in the modern sense that for each temperature there is a range of frequencies of which that existing in greatest intensity is characteristic of the temperature, but on the assumption that for each temperature there was one frequency only. When a hot body *A* radiated to a cold body *B*, the former emitted rays of a higher frequency which were "calorific" to *B* and *B* emitted rays of lower frequency which were "frigorific" to *A*. Rumford was further in error in supposing that fluids did not conduct heat; he was misled by the magnitude of the part played by convection and missed the relatively small part played by conduction in the experimental arrangements which he made. Dalton and others pointed out his mistake.

It will be remembered that Rumford discoursed widely on the consequences of the laws of heat displayed in natural phenomena. He discussed also the proper application of the laws to human activities, and it is not surprising to find him pointing out that if heat is to be prevented from passing between two vessels, one of them inside the other, it is well to silver the outside of the inner vessel and the inside of the outer ("Complete Works of Count Rumford", 2, 243). The same idea must have been put forward frequently when the main laws of heat were understood. For example, in a book written by Gompertz in 1850 (see letter by G. H. Gabb, *Daily Telegraph*, Oct. 12, 1935), a 'fireproof box' is described which is to consist of one metal box supported on springs within a second. The space between is to be evacuated of air to prevent conduction and convection, and the metals are to be well polished to prevent radiation. Probably the author of this idea never tried to carry it out, or he would have discovered the difficulties of construction.

Dewar was obliged to face those difficulties when during 1892–94 he was in urgent need of effective containers of liquid air. With characteristic drive and energy, he succeeded in obtaining all the vessels he wanted of many forms and sizes. One of the chief technical difficulties was naturally the join of the two vessels, inner and outer: it was difficult to get a join that could stand—as Dewar put it—"the torture to which the glass is put". A rubber cap was often provided if—in the case of the early vessels—it was necessary to pour the liquid air over the junction. The first vessels were made in London by Muller and by Gillingham: they were afterwards obtained in large quantities from Germany. Mr. George Gabb has told me that he helped Muller with some of the first silvering; and Mr. Gillingham has shown me some of the appreciative letters which Dewar wrote to him.

A very great improvement in the production and subsequent maintenance of the vacuum was made when Dewar made use of the absorbing power of charcoal. Dewar points out that Davy employed caustic potash to remove traces of carbonic acid left after his air pump had done its best: and further, that de Saussure in 1815 made an extensive examination of the absorbing powers of charcoal from different sources. Tait and Dewar used this effect in 1874; they found coconut charcoal to be the best. When large containers were required, especially during the War of 1914–18, it was necessary to make them of metal, as the mechanical strength of glass was insufficient. Without charcoal the vacuum in these vessels could not have been maintained.

Dewar made splendid use of his ingenious device. His experiments had a special directness, and some were of great beauty. It is so long since they were shown in the theatre of the Royal Institution that many may like to see them, either because they have not seen them before or because they remember when Dewar performed them. As the Institution still has the services of Mr. Green, who helped Sir James in much of his later work, it is possible to repeat them in good style, and I hope that this may be done shortly.

SOME BIOLOGICAL ASPECTS OF SOIL FERTILITY

BY PROF. W. NEILSON JONES

THE difficulties associated with their study have probably led to an under-estimation of the importance of the biological aspects of soil fertility compared with that of the purely physical and chemical factors. An outstanding difficulty is the impossibility of reproducing in pure cultures of soil organisms the conditions present naturally in the soil, and the danger of drawing deductions from such cultures as to what the behaviour of any organism will be in the soil, where it exists as a member of the mixed soil population in a continually shifting environment. Moreover, greatly as laboratory studies have advanced our knowledge of the processes of plant nutrition, they have usually failed to take full account of the complexities of the natural root environment engendered by the activities of various micro-organisms in the soil.

In the course of recent studies on the fertility of a particular soil*, methods of 'biological analysis' have been employed which are felt to be of considerable general interest in that they offer a new and promising means of experimental approach to certain aspects of soil fertility. These methods, which consist essentially in determination of the comparative reactions of the soil as a whole towards substances of known chemical composition or towards specific organisms, are yielding information as to the biological potentialities of different soils and as to the reactions taking place in them such as could not be obtained, it is believed, from study of soil organisms in pure culture alone.

The studies in question had their origin in an attempt to find a physiological basis for the behaviour of coniferous trees in certain areas of Wareham Forest, Dorset. But although these investigations have centred around the soil of this area, it should be clearly understood that this soil is not regarded as in any sense unique. It happens to be a rather extreme example of its type, and therefore specially favourable for study; but the same kind of reactions that are going on in Wareham soil intensively presumably occur in lesser degree in many soils. The phenomena associated with these soils are not of local interest only, but must be taken account of in any general study of soil biology or soil fertility.

A series of papers has already appeared bearing on Wareham Forest and describing the results of numerous experiments relating to this area[1]. It has been established that failure to make growth on the part of the trees, so strikingly apparent locally, cannot be attributed merely to poverty of nutrient salts, soil acidity, or other simple cause; and that the exceptionally good growth following upon application of certain organic composts cannot be ascribed to the available nutrients present in the compost dressing. The hypothesis was put forward that the local infertility on the area is due to toxic residues formed during decomposition of organic detritus by micro-organisms; and that the effect of the compost is to provide a substrate which, by altering the serial activities of the different soil micro-organisms, modifies the chain of reactions constituting humus decomposition; with the result that the final residues, instead of being toxic, are favourable to the growth of the trees, to the mycelial growth of the fungi associated with them as mycorrhiza-formers, and to the establishment and free-functioning of a normal and balanced mycorrhizal relationship.

It is proposed here to do no more than indicate the nature of the biological test methods employed which have served to establish the existence of soil toxins of biological origin. Experimental details must be sought in the papers to be published shortly.

Several independent lines of investigation have been followed.

(1) Observations of H. G. Morton have shown that a nutrient agar medium, buffered to pH 4·8, which develops a profuse growth of mycelium after infection from the air for a few moments, remains sterile indefinitely if spread as a thin film over Wareham soil. The conclusion is that something diffuses from the soil which inhibits fungal growth on the surface of the agar. (A standardized technique has been worked out by I. Levisohn in which chance infection from the air is replaced by inoculation from a pure culture.)

(2) Previous treatment of Wareham soil by heating, or with alcohol, etc., completely removes its inhibitory properties. This conforms to the view that the toxic substance is a product of some micro-biological activity in the soil.

(3) The toxic properties also disappear if the soil is allowed to dry out or is mixed with one of the composts alluded to above. Presumably these treatments provide conditions unfavourable to the toxic organism and/or favourable to other competing soil organisms.

---

* Financed by the Agricultural Research Council.

(4) Toxic Wareham soil, partially sterilized to remove its toxicity, regains its toxicity in about ten days after inoculation with untreated soil. This is confirmation that toxicity is associated with the activity of some organism.

(5) Small weighed samples of cellulose may be recovered unchanged after being buried four months in Wareham soil; similar samples undergo considerable or complete decomposition in fertile woodland soil, or in Wareham soil to which compost has been added, as a consequence of fungal attack. The inhibitory action of Wareham soil thus extends to the fungi responsible for cellulose decomposition. There appears to be a direct correlation between rate of cellulose decomposition in a soil and its fertility as measured by tree growth.

To summarize: it has been shown by these methods that Wareham soil and soils like it contain a 'toxin' which inhibits growth of fungi such as air-borne moulds and mildews; some, at least, of the mycorrhiza-formers; and those responsible for cellulose decomposition in the soil. It has also been shown that this toxin results from the metabolic activity of some organism, such activity representing a course of humus decomposition largely absent in fertile soils.

---

[1] Rayner, M. C., *Forestry*, 1934–39.

SURFACE TEMPERATURES OF THE STARS

THE abandonment of the 1939 British Association meeting at Dundee involved, among other things, the cancellation of what promised to be a discussion of great interest on the temperatures of stellar surfaces. Fortunately, however, Prof. W. M. H. Greaves's opening address on the subject appears in the October number of the *Observatory* magazine (62, 252; 1939). In his review of the present position, Prof. Greaves directs attention to the way in which recent observations—notably the colour temperature measurements carried out during the last ten years in England, Germany and France—have forced astrophysicists to the conclusion that no unique meaning can now be attached to the phrase 'the temperature of a star', because a stellar surface does not radiate even approximately as a black body.

The fundamental assumption of the early theory was that the total absorption coefficient of stellar material is not a function of the frequency of the radiation absorbed. The first deduction from this hypothesis is that the effective temperature of the radiation at any point in the star is equal to the temperature of the stellar matter at that point. From this in turn it follows that the star as a whole should behave very much as a black body, so far as its surface radiation is concerned; and on this conclusion is based the Fowler-Milne scale of ionization temperatures. But, unfortunately, the work on stellar colour temperatures developed at Greenwich, at Göttingen, and at Jungfraujoch leads to a totally different scale of temperatures. This disagreement between conclusions based on one hand upon direct experiment, and on the other upon an *ad hoc* hypothesis (for which little justification but mathematical convenience existed in the first place), has naturally proved fatal for the hypothesis.

The collapse of the assumption was not, however, entirely unexpected. The mere existence of discontinuities in stellar continua at the heads of absorption line series (notably at the Balmer limit) suggests that there is something seriously wrong with it. But in addition to this, the apparent breakdown of the Fowler-Milne scale of stellar temperatures has recently given an impetus to the mathematical investigation of various atoms with a view of determining if their absorption coefficients vary *between* the series limits. The work shows beyond doubt that such variation does exist, and it even predicts the type of variation for such simple atoms as those of hydrogen and the alkali metals. On the assumption that the absorption coefficient of hydrogen varies with the cube of the wave-length, Pannekoek (*Astrophys. J.*, 84, 481; 1936) finds that in an *A*0 star, where hydrogen is the main contributor to the spectrum, the colour temperature measured in the visual region should indeed be of the order of that observed, namely, nearly twice the effective temperature, simply as a result of this variation. At the lower temperatures of later-type stars, the more complex metallic atoms play a large part in the absorption; and beyond the qualitative result that the variation of metallic absorption coefficients with wave-length is in the opposite sense to the variation in hydrogen, little progress can yet be recorded in this direction.

Prof. Greaves concludes that future advances will call for contributions from the mathematician, in developing his treatment of the difficult general problem which allows for variability in the total absorption coefficient; from the physicist, in making laboratory measurements of the various atomic absorption coefficients; and from the astronomer, in devising and carrying out checks on theory as it develops.

A new method of obtaining the surface temperatures of stars directly from observation is announced by MM. Barbier and Chalonge in a paper following Prof. Greaves's address (*loc. cit.*, p. 273). These authors, recognizing the paucity of experimental information on atomic absorption coefficients, avoid their use altogether by dealing only with those early-type stars for which the total absorption coefficient is sufficiently great for the surface to radiate effectively as a black body. The criterion they use for selecting such stars is the size of the Balmer discontinuity: where this is large, the opacity below the Balmer limit will evidently be great. In this case there is a good chance that the radiation seen will originate mainly in the outer surface layers, the temperature of which will then be what is directly observed as the colour temperature of the star.

Evidence for this view is provided by observations of the eclipsing variable star Algol. The ultra-violet colour temperature of this star (which is typical, as to size of Balmer discontinuity, of the other stars considered) is found to be independent of the phase of the eclipse. Evidently the radiation from the centre of the disk is identical in composition with that from the limb (which is, of course, surface radiation). In this case, then, and by extension in the others also, the observed colour temperature is actually the effective temperature of the surface layers. The mean value for the A_0 stars selected is 12,500° K., which is in fair agreement with the ionization temperature.

This valuable method of attack thus brings still nearer the prospect of reconciling the various 'temperatures' which can be assigned to stellar surfaces. A. H.

OBITUARIES

The Earl of Crawford and Balcarres, K.T., F.R.S.

WE record with deep regret the death of the Earl of Crawford and Balcarres, which took place at Haigh Hall, Wigan, on March 8, at the age of sixty-eight years.

The Right Hon. Sir David Alexander Edward Lindsay was born on October 10, 1871, and succeeded his father in 1913 as twenty-seventh Earl of Crawford and as holder of other titles in the peerages of Scotland and the United Kingdom. He was educated at Eton and Magdalen College, Oxford, where he graduated in 1894 with first class honours in history. He afterwards entered upon a political career, and sat in the House of Commons, holding office on occasion, until he inherited the family titles. During the War of 1914–18 he served in France as a private and as a second lieutenant until in 1916 he was recalled to England to take up office as president of the Board of Agriculture and Fisheries. Later he held other offices in the Government, among them that of First Commissioner of Works, 1921–22.

Lord Crawford's interest in, and knowledge of, art and archæology were both widespread and profound; and in the performance of his duties as First Commissioner of Works, he was brought into close touch with conditions affecting archæological studies in Great Britain. Of this he made full and effective use both as president of the Society of Antiquaries and as a prominent figure in the various organizations which have had as their object the preservation of the antiquities, monuments and amenities of town and countryside in Great Britain. His charm and his personality, as well as his public experience and knowledge, made him an invaluable and most effective leader in any and every cause in which the interests of archæology were concerned, and it was owing very largely to his influence and persuasive powers that public and official interest in British antiquities was stimulated in post-War years to greater activity in archæological exploration and also in preserving such relics of the past as remain from an over-zealous desire for improvement or the inroads of commercialism.

Lord Crawford had already acquired a considerable reputation as a scholar in artistic and antiquarian studies, notably in the field of Italian art, before his official connexion with the Office of Works. He published his well-known "Evolution of Italian Sculpture" in 1910. He was a trustee of the National Gallery and the National Portrait Gallery, and in 1923 became a trustee of the British Museum. He was chairman of the Fine Art Commission and a member of the Royal Commissions on Historical Manuscripts and Ancient Monuments, as well as of the council of the British School of Archæology at Rome. His academic achievement and services to archæological studies were recognized by honorary degrees of the Universities of St. Andrews, Cambridge, Edinburgh and Manchester. Of the last-named University he was the chancellor, succeeding the late Lord Morley in 1923. As chancellor, he took a very keen and active interest in the affairs of the University. In the following year came his election as a fellow of the Royal Society.

Lord Crawford's death will be mourned on personal grounds by all who knew him; it is no less a serious loss to the cause of humane studies, and comes at a moment when so outstanding a personality can ill be spared.

Prof. F. P. Purvis

THE announcement of the death at Seaford, on February 20, of Prof. Frank Prior Purvis will be read with regret by all those interested in the progress of naval architecture, for he was the last surviving assistant of William Froude at the Admiralty Experimental Tank at Torquay.

Prof. Purvis was nearly ninety years of age, having been born on April 18, 1850. The son of Dr. Prior Purvis, he was educated at Blackheath School, and during 1867–70 was trained as a shipwright under the Admiralty at Deptford and Chatham Dockyards, and in the old Royal School of Naval Architecture and Marine Engineering at South Kensington. While passing through his training, he gained a Whitworth scholarship, being one of the first to do so. After a short time spent at the yard of Robert Napier on the Clyde, and on the staff of Sir Edward Reed, who in 1870 had resigned the post of chief constructor at the Admiralty, Purvis joined Froude at Torquay in 1871, and remained with him for six years. From Torquay he went to Govan, serving under Sir William Pearce, but in 1879 he became head of the scientific staff of Messrs. William Denny and Brothers, Dumbarton.

Froude had no greater admirer than William Denny III (1847–87), through whose initiative the firm constructed an experimental tank similar to, but slightly longer than, the Torquay Tank. This was the first tank to be erected by a shipbuilder, and the façade of it bears an inscription saying that it was erected in memory of Froude, "the Greatest of Experimenters and Investigators in Hydrodynamics". The first experiments were made in the tank in February 1883, and later tests proved of great value in the development of the designs for the cross-Channel vessels for which the firm is well known.

Leaving Dumbarton in 1889, for the next ten years Purvis was a partner in the firm of Blackwood and Gordon, Port Glasgow, and two years after severing his connexion with them he entered upon his long career of teaching in Japan.

The interesting story of the rise of engineering education in Japan dates back to the 'seventies of last century, when Dyer, Marshall, Alexander, Divers, Perry, Ewing, Ayrton, Milne and others went out from Great Britain to teach in the old College of Engineering (Kobu Daigakko), now a part of the Tokyo Imperial University, and when British naval engineers were lent to the Japanese Admiralty. Instruction in naval architecture was originally started in the College by the late Prof. S. Miyoshi, who had learnt shipbuilding under Robert Napier, but in 1899 the authorities invited Prof. P. A. Hillhouse to occupy the chair of naval architecture in the University, and it was his post to which Purvis succeeded in 1901.

Purvis held the chair for nineteen years, during which time, from a place of insignificance, Japan rose to be one of the chief shipbuilding countries in the world. From an output of about 3,000 tons in 1900, the tonnage launched rose year by year until in 1919 the output exceeded 600,000 tons. Early in the century, too, the Japanese Government built an experimental tank, 494 ft. long, at Nagasaki.

For his long services in Japan Purvis was decorated with the orders of the Rising Sun and Sacred Treasure. He was a member of the Institution of Civil Engineers, the Institution of Naval Architects and the Institution of Engineers and Shipbuilders of Scotland, to which he contributed a few papers.

The Rev. Hilderic Friend

THE REV. HILDERIC FRIEND died in his eighty-eighth year at his home in Solihull, Birmingham, after a long illness. He was born at High Wigsell in Kent in 1852, but spent his early years in the vicinity of Hastings and always regarded himself as a Sussex man. In 1874 he entered the Wesleyan College at Richmond to train for the ministry, and two years later he sailed as a missionary to China. Ill-health compelled him to return home in 1880 and, with a view to his recuperation, he was given a series of country circuits for his pastoral care. His first was at Newton Abbott in Devonshire, where he spent much time in the open air and began to study field botany systematically. Here he wrote "A Glossary of Devonshire Plant Names". This was succeeded in 1884 by "Flowers and Flower Lore" and by "The Ministry of Flowers" in 1885.

After travelling all over the country in his ministerial capacity, Mr. Friend retired in 1914. For many years he had interested himself in worms, and he now devoted his leisure to their more thorough study.

As the result of his labours science was enriched with the knowledge of many new species, and contributions from his pen have frequently appeared in the columns of NATURE. He was a voluminous writer, and was the author of more than a dozen books and of several thousand articles. In 1937 he successfully recovered from a serious operation, but a few weeks later his wife passed away. He never recovered from the blow. He died on February 7, leaving a son, Dr. J. A. Newton Friend, who is head of the Chemistry Department, Technical College, Birmingham, and a daughter.

WE regret to announce the following deaths:

Prof. W. C. Brøgger, rector of the University of Oslo and a foreign fellow of the Geological Society of London, on February 17, aged eighty-eight years.

Dr. R. T. Gunther, curator of the Oxford Museum for the History of Science, University reader in the history of science, on March 9, aged seventy years.

Prof. E. Maragliano, emeritus professor of clinical medicine in the University of Genoa, a pioneer in tuberculosis research, aged ninety-one years.

Prof. Károly Schaffer, emeritus professor of neurology and psychiatry in the University of Budapest, aged seventy-five years.

NEWS AND VIEWS

Phillippe de La Hire (1640–1718)

On March 18 the tercentenary occurs of the birth of Phillippe de La Hire, one of the most versatile of French men of science of the later half of the seventeenth century. The son of Laurent de La Hire, a famous painter, who died in 1656, he was instructed in art, but he also learnt mathematics from Gaspard Desargues, the friend of Pascal and Descartes. When twenty years of age, he went to Italy, where he spent four years. On returning to Paris, he resumed his mathematical studies and, during the next forty years, published many papers and books on geometry, conic sections, epicycloids, magic squares, and other subjects. His work on magic squares was based on the treatise of the fifteenth century Italian mathematician Emmanuel Moschopulus.

La Hire also, from 1683 onwards, made astronomical observations at the Paris Observatory, where the elder Cassini and Picard were similarly engaged, and with them, too, he carried out geodetical work for the map of France planned by Colbert. His physical work included researches on the variation of the compass, on refraction and barometric and thermometric measurements. He was elected a member of the Royal Academy of Sciences in 1678, and for a number of years held a chair in the Collège Royale de France. "Astronomer, mechanician, geometer, hydrographer," said Fontenelle, "he was an academy of sciences in one man". He was twice married and had eight children, of whom two, Gabriel-Phillippe (1677–1719) and Jean-Nicolas (1685–1727), were also members of the Academy of Sciences. La Hire died in Paris on April 21, 1718.

Jules Christian (1840-1907)

Dr. Jules Christian, an eminent French alienist, was born at Bischwiller in Alsace on March 16, 1840. He studied medicine at Strassburg, and for three years before graduating became a resident in the Stephansfeld Asylum (Bas-Rhin), which provided him with a rich field of psychiatric study. In 1863 he obtained the Esquirol Prize offered by the Société Médico-psychologique with an essay on the dura mater in the insane, and in the following year qualified with a thesis on hæmorrhagic pachymeningitis. During the Franco-Prussian War he took an active part in looking after the wounded, and after the peace of Frankfort in 1871 left his practice in Alsace and joined the staff of the Montevergnes Asylum in the Vaucluse Department, where he remained for nearly four years and made numerous contributions to the *Annales médico-psychologiques* and *Archives générales de médecine*, of which the most important were those on injuries in the insane, insanity following acute disease, and sensory changes in melancholia.

In 1876 Christian was appointed physician to the Maréville Asylum near Nancy, where he made a special study of general paralysis and epilepsy, and won the Falret Prize awarded by the Académie de Médecine by a work on epilepsy in relation to insanity. He also delivered a course of lectures at the time on mental disease, at the Nancy medical faculty, and would probably have been appointed professor in this subject, but in 1879 he was made physician to the asylum of Charenton, where he remained until his retirement in 1904. During this long period he made many more valuable contributions to the literature of mental disease, of which the chief were those on epilepsy and epileptic insanity, for which he gained a prize awarded by the Belgian Royal Academy of Medicine, and on dementia præcox. He died on July 11, 1907.

Countering the Magnetic Mine

According to the naval correspondent of *The Times*, a conspicuous feature of the *Queen Elizabeth* on her arrival at New York after her secret maiden voyage from the Clyde was a 'girdle' around her hull. This girdle is apparently the means of protection adopted against the magnetic mine. The girdle, supplied with electric current of the necessary strength and characteristics, sets up a magnetic field which, in association with the steel hull and other magnetic material of the ship, is such that magnetic mines laid at sea are not set off by the passage over them of a vessel so equipped. The apparatus is said to have been devised and developed by officers of one of H.M. naval establishments, with the advice and assistance of scientific men consulted for the purpose. It has been given the expressive name 'de-gaussing girdle', the aptness of which will be recognized by all with an elementary knowledge of magnetism.

Mr. Winston Churchill paid a tribute to this piece of work in his review of the war at sea when introducing the Navy Estimates in the House of Commons on February 27. He said, "We see our way to mastering the magnetic mine and other variants of the same idea. How this has been done is a detective story written in a language of its own . . . we do not feel at all outdone in science in this country by the Nazis." This is all the thanks which can be given at present for the work of some few of the men of science who have given up their investigations to put their special knowledge and skill at the service of the country. It is an achievement of high order to have devised protection against a relatively novel form of attack in so short a time, and should encourage the further use by the Government of scientific talent.

Blood Groups and Racial Diagnosis

In view of the stress laid by many anthropologists on the significance of the blood groups in the racial classification of man, attention may be directed to the results of certain investigations of the weak *A* reaction found in some cases of the group *AB* by G. L. Taylor,

R. R. Race, Aileen M. Prior and Elizabeth W. Ikin (*Brit. Med. J.*, Feb. 24, 1940). It had already been shown that in some *AB* cases the factor *B* is partially dominant to and obscures the *A* antigen; and that while there tends to be some weakening of the *B* reaction in group *AB*, it is nothing like so marked or so important as is the suppression of *A*. As there are two types of *A* antigen, A_1 and A_2, a stronger and a weaker, the suppression by *B* of an already weak A_2 in the group A_2B may result in it only being possible to detect the *A* factor with powerful anti-*A* serum, the cells otherwise being diagnosed as group *B*.

Following on the observations recorded, it is shown that the order of decreasing strength of reaction is A, A_1B, A_2, A_2B. Further, as the serum from quite a number of A_2B cases contains the antibody α_1, which reacts with A_1 but not with A_2 cells, unless appropriate measures are taken, a reaction will result which confirms the diagnosis of group *B*. In view of the significance attached in anthropological classification to the distribution both within a given population and geographically of the elements *A* and *B*, it is of interest and importance to note that cases diagnosed as *B* have been found on re-examination to belong to group *AB*, and an inspection of published figures from all parts of the world shows that in a large proportion of the series there is a real deficiency of the numbers in group *AB*. It is possible that herein lies a clue to the explanation of certain anomalies and apparent irregularities to be noted in studies of the groups as racial elements.

The Black Rat in Great Britain

NOT so long ago it was generally said that the black rat, *Rattus rattus*, had disappeared from Britain, ousted in unequal contest with the brown new-comer, *Rattus norvegicus*. But to most naturalists interested in the subject it was known that little centres existed in wide-scattered areas where a black rat could be found if it was wanted. Now Colin Matheson, in an interesting account of results derived from his own observations in Cardiff and from a *questionnaire* sent to medical officers of health in "approved ports", discloses a somewhat disturbing situation about the black rat, the carrier of the flea, which in its turn disseminates plague (*J. Anim. Ecol.*, 8, 76; 1939). Stringent regulations are in force to ensure that ships are kept free of rats, and that while ships are in port it should be made extremely difficult for inboard rats to make a passage to the shore. The result has been a general decline in the rat population of ships visiting Britain, although a number averaging 6–8 seems to be the irreducible minimum on rat-infested ships.

On shore, however, in spite of rat-weeks and rat-prevention measures, the number of black rats appears to be on the increase, the statistics for thirteen British seaports showing a rise from about 4,110 in 1929 to more than 6,437 in 1934 and 5,362 in 1937. Moreover, the shore companies appear to be extending their range from the neighbourhood of docks to city areas, in some of which they are well established, and are able to maintain themselves without further accessions from the dockyard immigrants. Of the three commonest races of the black rat the most frequent in British seaports is the typical black form, *R. r. rattus*, but curiously enough the brownish *R. r. alexandrinus* takes the lead in numbers in London and Plymouth.

Activities of Analytical Chemists

IN his presidential address to the Society of Public Analysts and other Analytical Chemists delivered on March 6, Prof. W. H. Roberts pointed out that there has been much less need in this War than in the last for the formation of *ad hoc* committees of chemists to deal with problems with which the Government departments found themselves faced, for much had been foreseen and provided for; and some of the departments had from the outset adopted the course of appointing to their staffs eminent outside chemists, who not only brought to the departments their own expert knowledge but also rendered the departments more accessible to suggestions and representations from outside chemical bodies. The compilation of the National Service Register by the Ministry of Labour, in which the Society had co-operated, had provided the Government with a source of specialized personnel. The conditions of appointment of gas identification officers needs reconsideration, especially in view of the duties now placed upon them in respect of preliminary food tests for gas-contamination. Referring to the Food and Drugs Act of 1938, Prof. Roberts said that the rationing of meat would probably lead to increased consumption of certain other foods, such as sausages and cheese, and regulations governing the content of meat in sausages and of water in cheese (particularly processed cheese) would therefore become very necessary.

The number of analysts and consultants in independent practice has diminished greatly in recent years, Prof. Roberts said, but in the public interest it is important that there should be a strong band of such chemists, not attached to any special interest, and it was therefore necessary to watch closely for cases of unfair competition by publicly supported laboratories. Speaking of the necessity of maintaining a high standard of efficiency amongst analysts, he expressed regret that no English university has yet inaugurated a chair of analytical chemistry, and also suggested that the universities should exercise more rigorous selection to ensure that only students having a real aptitude for the subject should be admitted to their courses. The roll of the Society now includes 886 names. The following officers for the year 1940–41 were elected: *President*, Dr. E. B. Hughes; *Hon. Treasurer*, G. Taylor; *Hon. Secretary*, Lewis Eynon.

The Ray Society

AT the annual general meeting of the Ray Society held on March 5, under the presidency of Sir Sidney Harmer, Lieut.-Colonel R. B. Seymour Sewell was elected a vice-president and Sir David Prain, Dr. R. W. T. Gunther (since deceased) and Mr. C. S. Todd new members of council. It was announced that the first volume of Prof. F. Balfour-Browne's "British Water Beetles" would shortly be issued to subscribers for 1939. The council, in its annual report, referred to the difficulties with which the Society is faced as a result of the War. The report continues : "The Council believe, however, that the work of the Society ought to be carried on as far as it is possible to do so in war time. In common with other scientific bodies, the Society has a definite function to perform in helping to maintain the continuity of our national life, of which its activities are a very small, but, as the Council believe, not a wholly negligible part. It is proposed therefore to go on with the publication of the works now being prepared, and the Council appeals to all members who are able to do so to continue their support of the Society."

Association of Scientific Workers: New Branch

THE recently formed Glasgow branch of the Association of Scientific Workers held its inaugural meeting in the Royal Technical College, Glasgow, on March 6. The proceedings opened with a display of films portraying the history of the vitamins and developments in the use of the cathode ray oscillograph. Dr. J. D. Sutherland, chairman of the branch, referred briefly to the aims and work of the Association and then called upon Prof. W. F. K. Wynne-Jones to deliver the inaugural address. Prof. Wynne-Jones led up to the general question of the organization of science and scientific workers by considering the planning of research. He said he is strongly opposed to the view that research should not be organized, and expressed the opinion that valuable results will only be obtained from an investigation if it is carefully planned beforehand. He contended that scientific research arises fundamentally from the needs of society, and illustrated his point with several very pertinent examples from the history of science. In furtherance of his argument for increased organization among scientific workers, Prof. Wynne-Jones spoke of the poor financial support received by research in Great Britain and of the muddles that had arisen at the outset of the War because men of science had not been called upon to organize services which belonged essentially to their province. Science can and must be organized, and to this end scientific workers must develop a corporate sense.

Rhodes Scholarships for India

THE Rhodes Trustees have decided to found two Rhodes Scholarships annually for India. The Rhodes Scholarships are of the annual value of £400, and tenable at the University of Oxford. With one or two exceptions they are awarded to young men who have been educated at universities in the British Dominions or in the United States of America. Cecil Rhodes laid down in his will that in the election of a scholar special regard should be paid to his scholastic attainments. his fondness for manly outdoor sports, his qualities of manhood, truth, courage, devotion to duty, unselfishness and sympathy for the weak, and his powers of leadership. The Rhodes Trustees are confident that candidates fully up to the high standard set by previous Rhodes Scholars will be forthcoming from India, and they have been assured that Indian Rhodes Scholars will be welcome at Oxford. These scholarships are founded for an initial period of five years, after which they will be reviewed in the light of experience. The first Indian Rhodes Scholars will go into residence at Oxford after the end of the War. This is the second announcement of post-graduate awards for Indian students which have been made in recent years ; it will be recalled that the Commissioners of the Exhibition of 1851 instituted exhibitions for India in 1937.

The Conception of the Atomic Clock

THE presidential address to the Section of Physics of the American Association for the Advancement of Science, which was delivered at Columbus on December 29 by Dr. Herbert E. Ives, is printed in *Science* (91, 79 ; 1940). The address is entitled "The Measurement of Velocity with Atomic Clocks". Taking the variation of atomic clock rate as an experimental fact, established by the Doppler effect in hydrogen canal rays, and adopting also the Fitzgerald contraction of moving rods indicated by the Michelson-Morley experiment, Dr. Ives points out that it is possible to define 'velocity' in various ways, none of which has any *a priori* claim to be chosen as 'correct'. The Restricted Theory of Relativity corresponds to the choice of one of them. "They are all deviations from the simple Newtonian concept of velocity", says Dr. Ives, "which is in terms of rods and clocks which are unaffected by motion. I urge the merit of the Newtonian framework as the only unambiguous basis for the idea of velocity". Dr. Ives does not consider that the ether has been "abolished" simply because it is possible to define velocity in a manner which makes it unnecessary to refer to that medium : he claims that the Sagnac experiment, in which beams of light moving in opposite directions round a rotating disk produce movable interference fringes, gives experimental evidence of the existence of the ether. His views, he says, "will be recognised as those of the earlier students of the subject—Fitzgerald, Larmor, Lorentz—but not of those who would shift the burden from variant measuring instruments to the nature of space and time".

Relativists will probably not be convinced by Dr. Ives's arguments. They will ask why, if there are invariant measuring rods and clocks, we cannot discover them but have to use those which vary with motion ; and further, why, of varying ones, we cannot tell in what state they approximate most closely to those which are immutable. It is to be noted also that Dr. Ives's address scarcely justifies the choice of title. An atom may be *conceived* as a clock, but cannot possibly be used as an instrument for measuring time or velocity unless we make an *ad hoc* definition of velocity in terms of wave-length changes and define an atom as a light-wave.

Treasure of Psusennes

Now that the sarcophagus of Pharaoh Psusennes found on the site of the ancient Tanis (NATURE, February 24, p. 300; March 9, p. 382) has been emptied of its mummy and associated jewellery, it has been possible to form a more just estimate of the magnitude of the find. It is regarded as one of the richest discoveries ever made after that of the tomb of Tutankhamen (*The Times*, March 7). In this collection of remarkably beautiful jewellery, some of the necklaces, as described, are outstanding. One, for example, is composed of two heavy bars of gold supporting a centre-piece in the form of a golden lotus, which is so heavy, it is said, as to emit a gong-like note when the necklace is shaken. Another necklace consists of several huge pieces of lapis lazuli with gold clasps, on which there is an inscription saying that the King had had made for him a necklace which never would be equalled. This necklace scales the remarkable weight of 12 lb. Among other objects of jewellery in the find are mentioned further necklaces, two bracelets, golden slippers with a golden case, pins and studs. All the antiquities found, with the exception of the granite sarcophagus, are being transferred to the Cairo Museum, where they will be placed on exhibition forthwith.

Meteorology in British East Africa

THE director of the British East African Meteorological Service, Mr. A. Walter, describes the work achieved by his Service in 1938 in his annual report for that year. Although described by him as an extremely difficult year, no hint of this would be obtained from a consideration only of the work achieved and the preparations made for extending and improving the activities of future years. Many of the staff fell sick because it had been impracticable for them to take the vacation leave to which they were entitled, and the training of all grades of staff had to be maintained; it was estimated that this would have to be continued for another five years before each section of the Service could become a fully efficient and self-contained unit.

There is much of interest both on the climatological and synoptic sides in this report, and evidence that important contributions to the understanding of meteorological processes are being made. During the course of the year the whole region, which includes Kenya, Tanganyika, Uganda and Zanzibar, has been divided up into zones characterized by peculiarities in the seasonal distribution of rainfall. Seven such zones were found sufficient to cover broadly the observed range of variation, and have been made the basis of a division of the country into forecast areas, which are shown on a map (p. 27). Both daily and weekly forecasts have been appreciated by the resident population and by visitors, an evidence of this interest being the suggestions received for increasing their frequency and extending their range. The weekly forecasts are based mainly on the relative positions of the high- and low-pressure systems on either side of the tropics and the probable changes in the main wind currents connected with them. They are described as an unqualified success, a fact which is modestly explained as being due to the circumstance that the effects of high or low pressure appearing off the west coast of Africa are generally felt about a week later in the tropical regions of East Africa.

Many planters have stated that their work is planned in accordance with the indications of the weekly forecasts. Local eccentricities of response to general changes are, however, an obstacle to accurate forecasting here as elsewhere, and it is stated (p. 25) that small short-period variations of pressure, temperature and upper winds are showing a significance which would be considered out of all proportion to their magnitude and duration in the meteorology of temperate regions. This report deserves to be regarded as a model for a young progressive meteorological service in the tropics.

Suggested Grid in the United States

CONFERENCES have recently been taking place in Washington with the officials of some fifty large public utility companies operating in the eastern part of the United States to explore the possibilities of constructing a series of high-voltage lines interconnecting the larger generating plants and power-consuming centres in this area, including both private and public developments. According to the *Electrical Review* of February 9, although up to the present no definite plan has actually been made public, the proposals include connecting links that would make it possible to interchange power whenever necessary between such major load centres as Boston, New York, Philadelphia, Washington, Buffalo, Cleveland, Detroit, Chicago, St. Louis, and possibly Birmingham. Connexions would be made with all major generating stations, both steam and hydro-electric, without regard to whether they are controlled by private capital, municipalities, or the Federal Government.

According to preliminary estimates, the construction would cost approximately £100,000,000. Objections to the plan have been raised owing to the ample generating capacity now in existence or under construction in each of the localities to meet possible future demands. It is also contended that the expenditure of such a large amount would impose an unnecessary financial burden upon consumers of electricity. The advocates of the scheme take the view that the future growth of power demand will be at an accelerating rate and that the rate of construction can be adjusted to actual needs for the new facilities. They are also understood to be relying strongly on the national defence argument, on the assumption that, even though temporarily uneconomic, the Grid can be justified as a safeguard against the power shortages experienced by American industry during the War of 1914–18.

New Radio Transmitter

ALMOST unnoticed in the unsettled international atmosphere that existed last August, an extraordinary radio transmitter was inaugurated in the pocket republic of Andorra, which bestrides a small section of the Pyrenees on the frontier between France and Spain. A brief account of this station is given in the *Electrician* of March 8. The President of the French Republic (as successor to the Kings of France) and the Bishop of Urgel in Spain share as co-princes the over-lordship of Andorra, a condition which has lasted since the early part of the ninth century. Radio Andorra is situated on a rocky hill at an altitude of 2,920 ft. above sea-level, but its aerial is placed at an altitude 2,460 ft. higher and is suspended across a lake; the supports, 410 ft. high, are 820 ft. apart. The feeder cable between the station and the aerial is 2,788 ft. long and is believed to be the only case in which a distance of this order separates a transmitter and its antenna, with the exception of the Eiffel Tower, where ultra-short waves had to be considered. At Andorra transmitters for medium and short waves are installed. The energy required for the station is 350 kilowatts and is obtained from the Forces Hydro-électriques de l'Andorra, a water-power undertaking, which sells the bulk of its production outside the borders of this small State.

Illness in Meat Packing Industry

IN a recent paper (*Public Health Rep.*, 54, 2196; 1939) Hugh P. Brinton, assistant statistician, Harry E. Seiffert, assistant public health engineer, and Elizabeth S. Frasier, junior statistician, United States Public Health Service, present an analysis of cases of sickness and non-industrial injuries lasting eight calendar days or longer among workers in the slaughter and meat-packing industry. The annual number of cases per 1,000 was 95·0 for white males, 144·2 for white females, and 137·9 for negro males, while the average number of days of disability per person was 3·16, 4·85 and 4·01 respectively. Those who showed the highest figures in the form of an excess of respiratory diseases were cold-meat workers among white males, scalers, wrappers and packers among white females, and by-product workers among negro males.

Very excessive rates for rheumatic diseases were found in certain occupations, especially those of warm- and cold-meat workers, sausage and casing workers, and curing workers. As regards environmental conditions, white males exposed to high humidity or wet had the highest rates, with non-respiratory and non-digestive diseases most in excess. Among white and negro males the highest incidence was found among those working in hides and wool, or glue and entrails, among whom digestive diseases were much commoner than the average. White males and white females showed sickness-rates in decreasing order of magnitude as follows: semi-skilled workers in manufacturing, labourers, and clinical workers.

New Seismographic Equipment in the United States

A NEW seismograph station has been established at Lincoln, Nebraska, and new equipment has been installed at Chicago, Salt Lake City, and Bozeman, Montana, all co-operating stations of the United States Coast and Geodetic Survey, according to J. H. Nelson and H. E. McComb. The new seismograph station is on the campus of the Nebraska Wesleyan University in Lincoln, Nebraska, and is situated on a layer of loess and glacial clay 150–175 ft. thick, under which is several hundred feet of Cretaceous sandstone. The position is latitude 40° 49·1′ N., longitude 96° 42·2′ W., altitude 358 ± 5 metres.

The seismograph operates as an east-west component and is a small experimental McComb-Romberg tilt-compensation seismometer having magnetic damping and a clock-driven completely enclosed recorder. Time control is furnished by a Seth Thomas pendulum clock compared daily with naval radio time signals from Arlington. Tilt compensating instruments have been installed at Chicago on account of the slow irregular tilt movements of the pier on which the seismographs rest. Salt Lake City (latitude 40° 45·9′ N., longitude 111° 50·9′ W., altitude 1433 ± 5 metres) had a two-component 100-kgm. Bosch-Omori seismograph and has recently installed a two-component small model McComb-Romberg tilt-compensation seismograph. At Bozeman, oil damping has been replaced by magnetic damping and the recording equipment has been improved.

Smoke Abatement

THE National Smoke Abatement Society has issued its quarterly, *Smokeless Air*, on a reduced scale but with a supplement "Smoke Abatement in War Time". This is an effort to rebut the belief that reduction of smoke under present conditions is unimportant. The impression that smoke serves a useful purpose by screening towns against air attack is challenged. A smoke screen may assist a moving object such as a ship, but serves as a landmark fixing the position of a stationary group such as a town. It may provide a screen to hinder the recognition of a specific object, but equally it conceals the attacker from the defence. Concealment is a great help to the submarine, and recent experience shows its assistance to raiding aircraft. The pamphlet directs attention to the way in which colliery tips serve as landmarks, providing a "difficult problem" in smoke abatement. The difficulty, it may be indicated, is less technical than political and due to the fact that the disposal of pit refuse is left to the discretion of the individual colliery. Naturally the cheapest possible method is used, regardless of the effect on the surrounding people, land and of the ultimate cost to the community. The chemical composition of pit refuse is such that self-ignition can scarcely be prevented when it is dumped in enormous heaps. Too often collieries are surrounded by low-lying land reduced to valueless swamp by mining subsidence. Pit refuse would serve a useful purpose, if used to raise the level of such land, and under such conditions firing would not occur.

Smoke results from the liberation of the volatile matter of coal, a large part of which is liquid. Smoke abatement is a movement for collecting this liquid for useful purposes instead of dispersing it as a public nuisance. Present conditions emphasize the wisdom of smoke abatement as a national defence measure. The national need for liquid fuel cannot, it is true, be met by the carbonization of coal, but the contribution is already by no means negligible. Already in 1938, 8 per cent of the motor spirit consumed in Great Britain was obtained from coal. The quantity of heavier oil suitable as fuel was of the same order. The pamphlet makes a plea for a planned fuel policy, saying that "smoke is a by-product of the technologically primitive phase of industrial civilization from which we have not yet emerged".

The Cooper Union

THE eightieth annual report of the Cooper Union for the Advancement of Science and Art covers the year ended June 30, 1939 (Pp. 122. New York, 1939). The report of the Director, emphasizing the extent to which industry is becoming more scientific, refers to the increase in basic instruction in science and mathematics in the engineering schools, and decreased instruction in detailed applications of engineering. Special stress is laid in this report on the integrated study of the social sciences, so as to develop the mind of the engineering student not only to think rationally and scientifically, but also to be able to grasp concepts that do not admit of the precise analysis, calculation and control with which the physical scientist and engineer have been accustomed to work and which have hitherto been the accepted limit of his knowledge and proficiency.

The Director considers that humanistic studies should be required throughout the four or five years of undergraduate training. Commenting on our failure to stir those interests which lead the engineering graduate to continuing his studies of science and society, he urges that the impasse which faces civilization to-day is due to our attacking our problem by rule of thumb, expediency and self-interest, instead of by the scientific method, which, if coupled with sensitivity to the human values of freedom and individuality, will save civilization from the irresponsible technologist and the scheming politician.

Control of Spirit

FOLLOWING the introduction of prohibition in Bombay, the Government has restricted sales, advertising and general dealing in all spirituous preparations containing more than 2 per cent by volume of alcohol. Recently, however, the Bombay Government has entirely exempted all toilet and cosmetic preparations containing alcohol from the prohibition regulations. It has also set up a Classification Committee to decide whether preparations which contain more than 2 per cent of alcohol can be used as beverages or not.

Non-Ferrous Metallic Ores

THE Minister of Supply has appointed a departmental committee to consider whether an increased production of non-ferrous metallic ores in the United Kingdom is desirable and practicable, and to make recommendations. The members of the committee are: Sir William Larke (chairman), Dr. C. G. Cullis, Mr. Arthur Deakin, Mr. J. Stanley Holmes, M.P., and Mr. S. S. Taylor. Prof. J. A. S. Ritson, Mr. T. Eastwood, and Dr. M. Macgregor will act as assessors to the committee. The secretary of the committee, to whom all communications should be addressed, is Mr. W. C. C. Rose, Geological Survey of Great Britain, Exhibition Road, South Kensington, London, S.W.7.

Colonial Appointments

THE following appointments and promotions in the Colonial Service have recently been made: H. K. Littlewood, veterinary officer, Nigeria; R. R. Temple, veterinary officer, Tanganyika Territory; C. L. Skidmore, agricultural superintendent, senior agricultural superintendent, Gold Coast; Dr. F. Dixey, director of geological survey, Nyasaland, director, Water Development Department, Northern Rhodesia; H. R. Binns, formerly veterinary officer, Nyasaland, veterinary research officer, Palestine; R. Leach, mycologist, Nyasaland, plant pathologist, Jamaica (temporary).

Announcements

THE tenth Joule Memorial Lecture will be delivered before the Manchester Literary and Philosophical Society by Prof. James Chadwick, professor of physics in the University of Liverpool, on March 19 at 5.30. His subject will be "New Applications of Physics to Medicine".

PROF. F. L. WARREN, formerly of the Fuad I University, Cairo, has been appointed professor of chemistry in the Natal University College, Pietermaritzburg.

THE fourth International Congress of Malaria will be held in Rome on the occasion of the International Exhibition of 1942.

THE Australian Commonwealth Government has set up a Central Medical Co-administrative Committee at the seat of Government at Canberra. The Committee will control all drugs and medical equipment so as to ensure the best use for the armed forces and civil population during war-time.

THE milk in schools scheme has been resumed for all children of school age, especially those in London. Voluntary milk clubs are being organized by teachers at schools and at certain other premises where children attend for some form of instruction. More than 200 of these clubs have already been formed and the number is growing almost daily. As in peace time, all children are asked to pay ½*d.* for each half pint of milk.

IN the article entitled "Food Production and Food Control" by Sir John Orr published in NATURE of March 9, p. 374, col. 2, last line of par. 3, the phrase "10 and 20 per cent" should read "5 and 10 per cent". This correction was received during the printing-off of the journal and was made in a part of the issue only.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

IN THE PRESENT CIRCUMSTANCES, PROOFS OF "LETTERS" WILL NOT BE SUBMITTED TO CORRESPONDENTS OUTSIDE GREAT BRITAIN.

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 429. CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Molecular Structure of the Collagen Fibres

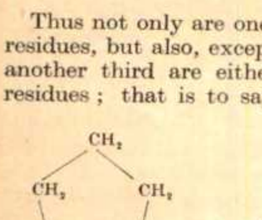
X-RAY studies of the fibrous proteins indicate that they fall almost exclusively into one or other of two main configurational groups, the keratin-myosin group and the collagen group[1]. The interpretation of the structure and properties of the former group is now well advanced and has frequently been reported on in NATURE and elsewhere, but the structure of the latter, in spite of many investigations, has hitherto remained unexplained. It was suggested several years ago that the amino-acid residues in gelatin (which also gives the typical collagen diffraction pattern) are somehow grouped in threes with probably every third a glycine residue and every ninth a hydroxyproline residue, that the strong meridian arc of spacing about 2·86 A. is associated with the average length of a residue in the direction of the fibre axis, and that such an average length could very well arise from an alternate *cis*- and *trans*-configuration[2]; but further progress was not possible for lack of experimental data. More recent chemical and X-ray evidence points now to a solution that is both simple and convincing.

(1) Bergmann[3] concludes that the average residue weight in gelatin is about 94, and that the chief residues are present in the proportions set out in the accompanying table:

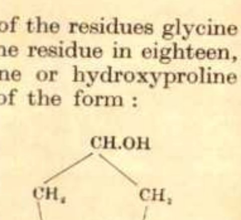
AMINO-ACID FREQUENCIES IN GELATIN

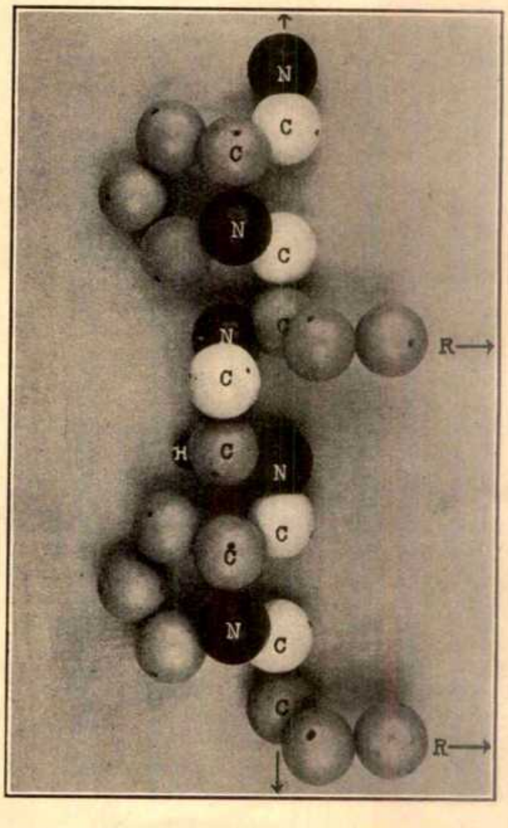
Amino-acid	Wt. %	Mol. Wt.	Gm. Mol.	Frequency
Glycine ..	25·5	75	0·34	3 $(2^0 \cdot 3^1)$
Proline ..	19·7	115	0·17	6 $(2^1 \cdot 3^1)$
Hydroxyproline	14·4	131	0·11	9 $(2^0 \cdot 3^2)$
Alanine ..	8·7	89	0·098	9 $(2^0 \cdot 3^2)$
Arginine ..	9·1	174	0·052	18 $(2^1 \cdot 3^2)$
Leucine-*iso*leucine ..	7·1	131	0·054	18 $(2^1 \cdot 3^2)$
Lysine ..	5·9	146	0·040	24 $(2^3 \cdot 3^1)$

Thus not only are one third of the residues glycine residues, but also, except for one residue in eighteen, another third are either proline or hydroxyproline residues; that is to say, are of the form:



or





The table shows too that there cannot be fewer than 72 residues in the gelatin 'molecule' (there will not be any definite molecule of gelatin itself, but only large, and possibly somewhat modified, fragments of the original collagen pattern): the true number must be a fairly high multiple of this, possibly 576, to judge by the histidine content for example.

(2) The side-chain and backbone spacings in dry gelatin are about 10·4 A. and 4·4 A., respectively, while the density is about 1·32 gm./c.c. Suppose these two spacings to be inclined at an angle β, and the average length of a residue in the direction of the fibre axis to be *L* A., then

$$94 \times 1{\cdot}65 = \frac{10{\cdot}4 \times 4{\cdot}4 \times L \times 1{\cdot}32}{\sin \beta}$$

that is, $L = 2{\cdot}6 \sin \beta$ (approx.),

and therefore *L* cannot be greater than about 2·6 A. This is only an approximate calculation, but it is sufficiently accurate to confirm that the strong meridian arc of spacing 2·86 A. is almost certainly associated with the average length of a residue.

(3) If it is actually equal to it, as seems most probable, and the residues follow one another in a row, then from the table the minimum length of the intramolecular pattern along the fibre axis is about 72 × 2·86 A. This length is not only too small to include the residues of other acids, such as histidine, omitted from the table, but also it is too small to account for the meridian spacings reported by Wyckoff and Corey[4] and by Clark and co-workers[5]. Their data are best explained by a sequence of 4 × 72 residues in a row, grouped in approximate sets of 12, 24 and 36. This gives a molecular weight of about 27,000, or a multiple thereof, corresponding to Svedberg's gliadin class[6].

(4) The proposed partial *cis*-configuration[2] is readily accounted for by the preponderance of imino residues. When we allow for this and the glycine content, there seems to be only one reasonable solution, represented by the scale model shown in the accompanying illustration. The basic sequence is *–P–G–R–*, where (with the exception of one residue in eighteen) *P* stands for either proline or hydroxyproline, *G* for glycine, and *R* for one or other of the remaining residues. The full-length pattern, and also variations within the collagen group as a whole, must arise by suitably modifying this simple theme.

Using the interatomic distances found in silk fibroin, the average length per residue in the pattern shown in the illustration works out to be 2·85 A., almost exactly the spacing of the strong meridian arc. Other points in favour of the model are: (*a*) there is no steric interference between the side-chains, the longer side-chains all lying on the side of the main-chain remote from the rings, leaving only the unobtrusive glycine side-chain (*–H*) on the same side as the rings; and (*b*) the polypeptide chain proceeds in a straight line, and any attempt to stretch it results in the side-chain (*–R*) swinging over towards the rings and the system coiling back upon itself: thus we have an explanation of the paradox that though the collagen configuration is shorter than that of the β-proteins, it is nevertheless practically inextensible.

The above solution of the collagen problem permits now of the broad generalization that all the extended forms of the fibrous proteins fall into either of two classes: they are built from polypeptide chains in either the *cis*- or the *trans*-configuration.

A fuller account of this investigation may be found in the first Procter Memorial Lecture[7], and a more detailed discussion still will be published elsewhere.

Capture Cross-Sections for Thermal Neutrons in Thorium, Lead and Uranium 238

EXPERIMENTS on the processes arising in thorium under neutron bombardment have shown that nuclear fission is induced only by fast neutrons of energies of about 2 Mev. or more. There exists also a radiative capture process producing an isotope of thorium (Th 233) of 26 min. half-life; this process has a resonance character with a large contribution from thermal neutrons[1]. So far, the capture cross-section of thermal neutrons in thorium has not been measured. The following experiments were carried out in order to determine this cross-section.

As the neutron source available was not very strong (100 mgm. Ra + Be), all dimensions had to be kept as small as possible. On the other hand, in order to obtain high accuracy of measurement, one had to use an absorbing thorium layer of reasonable thickness. By the kindness of Prof. Coster, I obtained a sample of metallic thorium of more than 99 per cent purity. Dysprosium of the highest purity, also kindly given me by Prof. Coster, was used as detector. The thorium was almost exactly prismatic in form (1·2 cm. × 1·2 cm. × 2·96 cm.). The dysprosium was a thin layer (15·7 mgm./cm.^{2} Dy) of rectangular form, 1·0 cm. × 2·7 cm., and its upper face was covered with 2 μ 'Cellophane'. For the absorption measurement the thorium was placed directly on the dysprosium with or without a cadmium screen, so that the neutrons impinging normally had to go through 1·2 cm. thickness corresponding to 13·4 gm. thorium.

The experimental arrangement was as follows. In a plate of paraffin wax of 3·8 cm. thickness, there was cut out a rectangular cavity of 1·3 cm. depth, the bottom and sides of which were covered with cadmium of 0·5 mm. thickness so that thermal neutrons could not enter except from above. This plate was put between two other plates of paraffin wax, forming in this way a block of 11·5 cm. height and about 25 cm. × 25 cm. area. The dysprosium was placed on the cadmium-shielded bottom of the cavity. The upper paraffin plate contained the neutron source 3·3 cm. below the surface in such a way that the source just touched the upper edges of the cadmium screened cavity.

The activity of the dysprosium detector was measured with a Geiger-Müller counter with 0·1 mm. aluminium walls connected to an amplifier. The dysprosium, the half-life of which was carefully determined and found to be 156 ± 3 min., was in all experiments irradiated up to saturation, and the decay of the activity was followed for several hours in order to increase the accuracy of measurements. All measurements were referred to a uranium standard. The contribution from thermal neutrons was determined by carrying out the irradiation with and without 0·5 mm. cadmium directly over the exposed face of the detector. With cadmium screens on all faces of the detector, the observed activity is due to neutrons faster than thermal neutrons. Under the experimental conditions used here, it amounted to 9 per cent of the activity obtained without cadmium on the exposed face.

For the determination of the capture cross-section for thermal neutrons in thorium, one has to consider the different kinds of interaction of neutrons with the thorium nucleus. The fission cross-section of fast neutrons is so small as to be negligible. The same holds for the radiative capture cross-section of fast neutrons. Therefore for fast neutrons one has to take into account the scattering cross-section only. Because of the arrangement used—the absorber being put directly on a detector of nearly equal size—one would expect that practically all the scattered neutrons would be efficient in the irradiation, that is, the scattering cross-section would not enter into these measurements. Experiment confirmed this expectation. When the detector was screened on both faces by cadmium, the measurements of the activity with and without thorium (or with and without lead) gave the same values within the experimental error of 2–3 per cent. Further, in order to test the influence of inelastic scattering, the cadmium was placed by turns either directly on the exposed face of the detector (with the thorium put upon that), or between the neutron source and the thorium absorber. No difference could be detected. Thus the inelastic scattering does not give rise to thermal neutrons in any observable quantity, a result to be expected.

These results suggest that, under the conditions actually used, the scattering of thermal neutrons too will be negligible, and thus the decrease in activity (of about 28 per cent) caused by the thorium absorber is due to radiative capture processes only. To obtain a direct proof the absorption in metallic lead was measured. The lead absorber had practically the same dimensions as the thorium absorber, but the thickness of the cast lead prism of density 10·6 was kept a little smaller (1·10 cm.) in order to have the same number of absorbing nuclei per cm.^{2}.

Of course, in determining the cross-sections, the angular distribution of the thermal neutrons was taken into account and obliquity corrections (angles up to nearly 70° were involved) were made according to the data given by Frisch[2].

The total cross-section for thermal neutrons in lead was found to be $\sigma^{th}_{\mathrm{Pb}} = 2{\cdot}5 \pm 0{\cdot}2 \times 10^{-24}$ cm.^{2}. This value is in very good agreement with the value of $2{\cdot}3 \times 10^{-24}$ cm.^{2} obtained by Fleischmann[3] from γ-ray measurements. Thus one can be sure that for thorium too the radiative capture cross-section alone enters into the measurements. The value obtained is $\sigma^{th}_{\mathrm{Th}} = 6{\cdot}0 \pm 0{\cdot}3 \times 10^{-24}$ cm.^{2}. This cross-section can be used to evaluate the capture cross-section of ^{238}U. In this isotope, as Bohr[4] has emphasized, thermal neutrons do not produce fission processes. Thus when equal small quantities of uranium and thorium are subjected to neutron bombardment under identical conditions, ^{239}U and ^{233}Th respectively being produced, it is clear that if on account of their nearly equal half-life the efficiency of the β-rays is assumed to be approximately the same, the β-ray activities due to thermal neutrons (corrected for equal numbers of nuclei) must be proportional to the respective cross-sections :

$$\frac{T^{th}_{\mathrm{U}(239)}}{T^{th}_{\mathrm{Th}(233}} = \frac{\sigma^{th}_{\mathrm{U}(238)} \cdot \frac{1}{238}}{\sigma^{th}_{\mathrm{Th}} \cdot \frac{1}{232}}$$

From earlier measurements carried out in Dahlem, I find for this ratio the value 1/4·15. Using the above value for the cross-section of thorium, the cross-section for uranium 238 is

$$\sigma^{th}_{\mathrm{U}(238)} = 1{\cdot}5 \pm 0{\cdot}2 \times 10^{-24}\ \mathrm{cm.}^2.$$

Anderson and Fermi[5], measuring directly the β-ray intensity of ^{239}U due to a known number of thermal neutrons, found

$$\sigma^{th}_{\mathrm{U}(238)} = 1{\cdot}2 \times 10^{-24}\ \mathrm{cm.}^2.$$

Considering the possibility of fairly large errors in this type of measurement, the agreement is very good.

I wish to express my gratitude to the Academy of Sciences for a grant and in particular to Prof. Siegbahn for the facilities kindly put at my disposal.

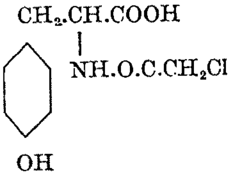
Mechanism of Catalysis by Enzymes

WHILE it is generally agreed that enzymes are true catalysts, the explanation of the mechanism of the reaction is still speculative.

In a previous paper[1] a theory was suggested to explain the catalysis and its reversibility. According to this theory the enzyme, having combined with its substrate, transmits to it a small quantity of energy which activates the substrate by altering the electron distribution in it. The altered electron distribution, by increasing the reactivity of the substrate, increases the reaction velocity. As the reaction proceeds and energy liberated by the formation of new bonds appears the energy borrowed from the enzyme is returned ; the whole mechanism being reversible. While the picture is too static to be strictly accurate and while the mechanism of electron distribution alteration is speculative, it is to be expected from this theory that there would be a relation between the polar constitution of the substrate and the velocity of its hydrolysis in the presence of an enzyme. The electron distribution in a compound depends partly on its polarity.

Abderhalden and Abderhalden[2] have shown that in the presence of acylase, chloracetyl-tyrosine (I) is



I

hydrolysed faster than the corresponding bromo compound, which is hydrolysed faster than the corresponding iodo compound. The important difference between these compounds is the polar contribution of the halogen, which is strongest in the chloro compound and weakest in the iodo compound. This case shows clearly the important influence which substrate polarity has on the velocity of enzymatically catalysed reactions. Abderhalden and Abderhalden have also shown that chloracetyl-, bromacetyl- and iodoacetylleucine under the influence of acylase behave similarly to the corresponding tyrosine compounds.

Glick[3], in studies on the specificity of choline esterase, has shown that halogenation of the acid component of acetylcholine increases the velocity of the catalysed reaction. He has also shown that halogenation of both radicals of ethylacetate considerably increases the velocity of the enzymatically catalysed reaction. Commenting on the fact that acetylcholine and chlorethylacetate are split at approximately the same speed, he states that it is peculiar that replacement of the positively polar methylamino group by the negatively polar Cl atom should not influence the reaction velocity. The fact that both these groups are electron attracting groups and exert negative inductive effects on the atoms of the link split explains this apparent anomaly. These examples from Glick's work also show the influence of substrate polarity on the velocity of enzyme action.

That substrate polarity is a factor determining quantitative enzyme specificity is clear from the marked effect which it has on the reaction velocity. Whether substrate polarity can be regarded as a factor determining absolute specificity remains to be seen.

Up to the present there have been many references in the literature to the importance of molecular polarity in biochemistry without any very clear reasons being given. When the influence of polarity on both the uncatalysed reaction (*cf.* Hinshelwood *et al.*[4]) and on the catalysed reaction is borne in mind the significance of this factor becomes clear. For example, changes in the polarity of a drug or other compound can effect its solubility, the rate and magnitude of its action and the rate at which it is destroyed whether enzymatically or otherwise.

Influence of Cell Wall Composition on the Moisture Relations of Hardwood Timbers

It has already been shown that the compressive strength of hardwood timbers in the green condition is dependent on the degree of lignification as revealed by the behaviour of thin sections with micro-reagents. Thus tropical timbers, with their greater degree of lignification, are on the average stronger than temperate zone timbers of similar density, and the normal wood of temperate zone hardwoods is stronger than tension wood from leaning trees of the same species[1]. The difference in strength between normal and tension wood was found to be less pronounced in air-dry than in green wood[1], and this observation suggested that the influence of the degree of lignification is affected by the moisture content of the wood. In order to examine this possibility a scrutiny has been made of data in the records of this Laboratory or published by other institutions[2,3,4]. The data were taken as a whole, without the exclusion of particular species, and a comparison was made (*a*) between tropical and temperate zone timbers, and (*b*) between normal and tension wood, the influence of density being taken into consideration. In so far as differences in cell wall composition account for the differences between the properties of the timbers under comparison, our observations indicate that the proportional increase in strength which usually accompanies the drying of wood is less in strongly lignified than in weakly lignified material, and consequently differences in strength which are due to differing degrees of lignification tend to be reduced as wood dries. This provides a partial explanation of the fact that the relationship between compressive strength and density is much closer in air-dry than in green wood, particularly in the case of temperate zone timbers.

It was further observed that tropical timbers show a slightly, but significantly, smaller shrinkage both radially and tangentially than temperate zone timbers; they have on the average a lower fibre saturation point (as determined from measurements of shrinkage in drying wood), and reach equilibrium at a lower moisture content when placed in an atmosphere of 90 per cent relative humidity. At 60 per cent relative humidity, however, there is no significant difference between the equilibrium moisture contents of the two groups of timbers.

The data available for the comparison of normal wood with tension wood are very limited in amount, but so far as they go they appear to indicate a behaviour parallel to that of the tropical and temperate zone timbers. The only difference of note is that in two of the three species examined the normal wood showed a slightly *higher* equilibrium moisture content at 90 per cent relative humidity than the tension wood; in the third species no difference was detected. In view of the small number of samples available, however, this point requires further investigation.

It is thus apparent that the equilibrium moisture content, the shrinkage in passing from the green to the air-dry state, and the strength-density ratio in hardwood timbers are all dependent to some extent on the degree of lignification. The influence of the degree of lignification on strength, however, appears itself to be dependent on the moisture content. It is of practical significance that variation of certain properties tends to be reduced as wood dries from the green state to the condition in which it is ordinarily used.

Details of the investigation are contained in Project 18, Progress Report No. 11, copies of which will be obtainable from this Laboratory.

Pigments of Sponges

The lipochrome nature of the colouring matters of the Porifera or sponges was recognized by Krukenberg[1] who refers to their carotinoid-like and rhodophane-like pigments, the latter being characterized by the possession of a single absorption band. Later spectroscopic study of the pigments of additional species by MacMunn[2] confirmed these observations.

More recently, Karrer and Solmssen[3] have isolated the Crustacean pigment astacene from the sponge *Axinella crista-galli*. They claim that this pigment is also present in *Suberites domuncula*, but this is at variance with an earlier observation of Kuhn, Lederer and Deutsch[4]. No other crystalline carotinoid had so far been isolated from sponges.

We are at present engaged on an investigation of the pigments of the red sponge *Hymeniacidon Sanguineum* (Grant). We have failed to detect astacene but have isolated two carotinoids, echinenone and γ-carotene in crystalline form. We have also obtained spectroscopic evidence of the presence of α-carotene. Echinenone was discovered by Lederer in 1935, who isolated it from the sea-urchin *Echinus esculentus*. Apart from β-carotene it was the first animal carotinoid found to possess vitamin A activity[5].

The demonstration of the presence of the pigment echinenone in sponges provides a chemical link between the otherwise unrelated Porifera and Echinodermata. It would also appear that this is the first occasion on which γ-carotene has been isolated from invertebrates.

We hope to publish a detailed account of this investigation elsewhere.

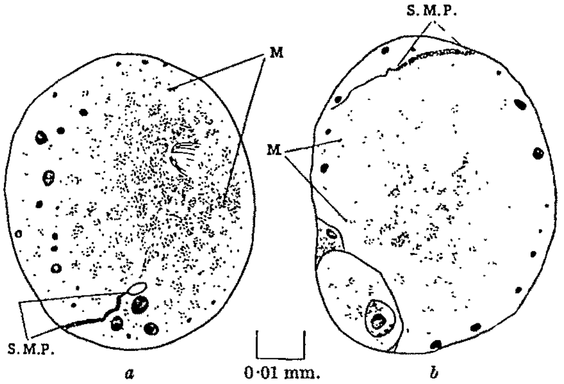
Presence of the Sperm Middle-Piece in the Fertilized Egg of the Mouse (*Mus musculus*)

During an investigation of the cytoplasmic inclusions of the fertilized egg of the mouse, the sperm middle-piece, and in some cases the whole tail, was observed in the ooplasm (*a* and *b*). The middle-piece usually becomes detached from the sperm-head shortly after the entry of the sperm, but may remain attached until the stage of the pronuclei is reached. The middle-piece is, at first, compact and deeply stained, but soon shows a granular structure. These granules are identified as the mitochondria of the sheath of the axial filament (*a*, *S.M.P.*). After the middle-piece is free of the sperm-head the sheath becomes less compact, so that the individual granules can be identified with ease (*b*, *S.M.P.*).

The sperm-mitochondria are slightly larger and are more deeply stained than those of the egg (*M*). At a later stage the mitochondria of the sperm stain in a similar manner to those of the egg; they now form a loose broad band, and are, later, distributed through the ooplasm.

Sperm-mitochondria were not identified during the later phases of the stage of the pronuclei, or during the first cleavage division, or in the two-cell stage.



It is concluded that the sperm-mitochondria become similar in size and staining properties to those of the egg, that they are distributed through the ooplasm and, later, become arranged around the spindle, together with the egg-mitochondria, and are consequently transmitted in approximately equal quantities to the first two blastomeres.

There is also evidence that the Golgi material of the sperm is carried into the egg. It undergoes fragmentation and becomes indistinguishable from the Golgi elements already present in the egg.

The present findings do not support the work of Lams[1], Levi[2], and Van der Stricht[3], who claim that the sperm-tail of certain mammals is segregated into one of the blastomeres of the two-cell stage.

So far as I am aware, distribution of the sperm-mitochondria through the ooplasm before the first cleavage division has not previously been recorded in the eggs of mammals. Held[4] and others, however, have traced the history of the sperm-mitochondria in the cytoplasm of the ova of certain invertebrates.

The present findings are based on the examination of material fixed in Flemming's fluid (without acetic), and of material treated according to the method of Aoyama. It is hoped to publish a detailed account of the history of the cytoplasmic inclusions of the sperm in the cytoplasm of the egg of the mouse.

Subjective Judgments of 'Firmness' in Elastic and Viscous Materials

In the testing by handling of many industrial products showing both elastic and plastic properties (of which cheese is typical), direct comparisons of 'firmness' are regularly made, although the physical dimensions of the property assessed as 'firmness' are variable. (No satisfactory theory of psychological dimensions has yet been proposed though these certainly differ from physical dimensions.) A study of this phenomenon is being published elsewhere, and in the course of the work it was found that even in the extreme case of truly fluid bitumen cylinders and approximately elastic rubber cylinders of the same size and shape, all the twenty subjects tested were able to give direct simultaneous comparisons for 'firmness'. With one exception, it was only after a considerable number of tests that subjects appreciated the dimensional difficulty, though 'firmness' has in the former material, the dimensions of a viscosity ($ML^{-1} T^{-1}$) and in the latter, those of a compression modulus ($ML^{-1} T^{-2}$).

It was also found that, over a considerable range of modulus and viscosity, a reversal in judgment could be produced by varying the time during which the handling was carried out. This effect was anticipated, since the dimensions of viscosity and compression modulus differ by T^{-1}, but it seemed worth while to carry out a quantitative experiment.

For this purpose, two of our best subjects were chosen. They were given pairs of cylinders, one bitumen cylinder and one rubber (diameter 2·0 cm., height 2·5 cm.), one in each hand, and instructed to squeeze each pair twice in time to a metronome, to change hands, to squeeze twice again, and to give a judgment as to relative 'firmness'. Adequate precautions were taken to eliminate extraneous effects. Times of 0·5 sec. and 4·0 sec. were used, the order of the tests being randomized.

First, a cylinder of truly fluid bitumen (viscosity, 10·7 × 10^6 poises) was compared with a series of rubber cylinders (compression modulus range, 0·78–1·41 × 10^7 dynes/cm.^{2}). In a second experiment, a single rubber cylinder (modulus, 1·53 × 10^7 dynes/cm.^{2}) was compared with a series of bitumen cylinders (viscosity range, 4·6–19·8 × 10^6 poises). The results of these tests are given in the accompanying table.

		Constant viscosity (bitumen)		Constant modulus (rubber)	
		4·0 sec.	0·5 sec.	4·0 sec.	0·5 sec.
1 (male)	Bitumen softer	30	3	25	7
	Rubber softer	1	16	0	19
	Indistinguishable	1	13	7	6
2 (female)	Bitumen softer	31	9	24	15
	Rubber softer	1	23	8	17
	Indistinguishable	0	0	0	0

The effect of varying the pressure of handling was also tested, but found to be insignificant.

A detailed examination of the data summarized in the table indicates that for an eight-fold time difference, the range of viscosity over which a reversal of judgment can be obtained in comparing a series of fluids with a standard elastic sample, shows no marked difference from the range over which the compression modulus of elastic bodies can be varied to give reversals in comparison with a constant fluid sample. Our previous work[1,2] has shown that the compression modulus of elastic materials can be judged subjectively some three times as accurately as can the viscosity of true fluids of the same order of 'firmness'. This depends on the fact that the elastic modulus can be judged statically whereas the viscosity demands a dynamic judgment. When elastic and viscous bodies are simultaneously compared, a dynamic judgment is required throughout.

The Nature of Time

IN a recent article, entitled "The Relativity of Time", Prof. Herbert Dingle[1] discussed what constitutes a clock, and he used the discussion to support a thesis which he stated at the outset, namely, that the restricted theory of relativity does not imply a Fitzgerald contraction of time intervals.

Prof. Dingle's conclusions in this regard are untenable, and in order to make clear the errors in his arguments, I shall first state some of the cardinal features of the restricted theory of relativity.

Two inertial systems $O.\ xyzt$ and $O.'\ x'\ y'\ z'\ t'$, with x-axes coinciding, are assumed to be moving relative to each other with a constant velocity, v, say. Then the co-ordinates x, y, z, t and x', y', z', t' are related by the Lorentz equations, and it follows that space intervals and time intervals in either system are reduced by the Fitzgerald contraction factor when observed by an observer at rest in the other system.

The time co-ordinate in each system is given by some cyclic or recurring phenomenon. Fundamentally its nature is that of a dial reading which indicates 'how many'. It is a reading which is observable by each observer in his own system, and is used to designate the temporal order and spacing of the reception and sending of signals.

Consider, then, Dingle's hour-glass type of clock, in which he says either the number of grains N, or the mass of sand MN, M being the mass of a grain, could equally well be regarded as measuring the time. In the second alternative, however, it is not legitimate to measure the total mass in one system in terms of the unit mass of the other, and to use this as time measure, as Dingle has done. Without the Lorentz equations there would be no basis for making such measurements, and therefore the Lorentz equations could not be derived from observations based on time obtained from mass measurements of this kind. Such time measure is alien to relativity and is inconsistent with the Lorentz equations.

Mass could be used to measure time if the man at rest with the clock did the measuring in each case. Thus, if M were the mass of a grain in the first system as measured by an observer in that system, then M is also the mass of a grain in the second system as measured by an observer in the second system. Therefore, if N and N' are the number of grains observed in each, then the masses observed are MN and MN'; and therefore whether the number of grains or the mass of the sand is used as time measure, the clock ratio is the same, namely, N'/N.

Consider now Dingle's second type of ideal clock, namely, "a particle . . . moving freely along an infinite space-measuring scale in a region free from gravitational and other fields of force, the time . . . (being) the reading of the scale at the instantaneous position of the particle". Regarding two such clocks he says, "the time which the stationary clock takes to move over n divisions of its scale must be considered equal to the time which the moving clock takes to move over n divisions of *its* scale. But the latter scale is contracted. . . . Hence the particle of the moving clock moves a shorter distance in the same time; that is, the moving clock must be considered to be running slower than the stationary clock. . . ."

This reasoning is fallacious. For the scale readings *are* the times with which relativity deals, and by the Lorentz equations their rates of change in the two systems are not equal. Also, to say that "the moving clock moves a shorter distance in the same time" is to define the time by the *distance* the moving particle has gone, and then to measure the distance on the *moving* scale by the unit length of the *stationary* scale. This is the same kind of error as was made in measuring the mass of sand in the moving system in terms of unit mass in the stationary system. The time in each system would be identified with the distance travelled by the moving particle if, and only if, the distance in each system were measured in terms of the unit of that system.

The question of the distortion of lengths and time intervals in relativity is one of some perplexity. In both cases it is manifested by light signals, but there is an important difference. In the case of rods, if they were of the same length when relatively at rest, they would appear distorted when in motion, but on coming to rest again they would show equality. In the case of the time intervals of separation, on the other hand, signals are continually received during the separation, and the time interval registered by the moving system is indicated by the accumulation of these signals. The whole rod comes back simultaneously, but the record of the travelling clock is received over the whole interval of separation, and a signal once received is never eradicated.

Dingle says that the time distortion cannot be exhibited experimentally, and with that statement I agree. The special theory of relativity deals with uniform relative motion, and a body under such motion cannot make a 'return trip' from another body. But I have made an extension[2] of the Lorentz transformation to accelerated motion, and this extension makes it possible to consider a return trip. The validity of the extension is confirmed by the consistency of the results from the point of view of observers in the two systems, and also by their agreement with the treatment of time distortion by the general theory of relativity[3]. The conclusion is that while the rod on returning has the same length as the one which remained stationary, the total recorded time of this moving system is less than the total recorded time of the stationary system; that is, the time distortion is real.

J. W. CAMPBELL.

Department of Mathematics,

[1] NATURE, 144, 888 (1939).

[2] Campbell, *Phil. Mag.*, (vii), 16, 529 (1933).

[3] Campbell, *Phil. Mag.*, (vii), 15, 48 (1933).

I CANNOT accept Prof. Campbell's criticism, which seems to me to be inconsistent. Apparently he holds that the time of an event is, *by definition*, a dial reading ("Fundamentally its nature is that of a dial reading": "the scale readings *are* the times . . ."). He agrees, however, that "the time distortion cannot be exhibited experimentally". Hence there is no evidence for a change of dial reading (that is, of that which by definition is the time). What, then, is this "time distortion" which he accepts?

Prof. Campbell misrepresents me in his first paragraph. I did not say that a definite contraction of time intervals was not implied: I said that a moving clock would not necessarily exhibit such a contraction. In that lies the main point of my article, which was intended to remove a general notion that measuring time is identical with reading the dial of an unspecified instrument. This notion appears to be even wider-spread and deeper-seated than I imagined, and as I believe it to be erroneous, I venture to give my reasons at some length.

The fundamental unit of measurement in physics is the unit of length: it is the distance between two marks on a bar kept under fixed conditions. The unit of time is the time taken by a specified moving body (one undisturbed by forces, according to Newton's First Law) to cover unit length. The unit of mass is defined in terms of the units of length and time (according to the principle of conservation of mass and momentum in elastic impact). All other units are chosen in terms of these. The unit of length is thus the only one which is chosen without reference to any other unit.

It follows that while the distance between two points can be measured by taking a particular body—the standard bar (which is chosen with some arbitrariness, though not, of course, without regard to convenience and the simplicity of the relations in which measures of length take part)—and laying it along the line joining the points, each other physical quantity can be measured only by first constructing an instrument *according to the principle by which the unit is defined*, and then, if necessary, correcting its readings for any failure of the instrument to incarnate that principle in whatever particular circumstances it is used. In making a measurement, therefore, we must discover not the dial reading but the reading which the dial would record if the principle were faithfully expressed.

The measurement of temperature affords a good example. On the air scale we define the unit interval of temperature as that which produces a given increment of volume in a given mass of air at constant pressure. The reading of the instrument rarely, if ever, corresponds to this, and we correct for expansion of the containing vessel, barometer variations, exposed stem, etc., to obtain the temperature according to the specified principle. There are other scales embodying other principles; for example, the mercury-in-glass scale, platinum resistance scale, etc. The readings of instruments intended to record these scales have similarly to be corrected, and the corrected results differ for the different scales. None of them, however, is the 'temperature' implied in physical theory. That is defined in terms of the 'absolute' or 'work' scale. It is impracticable to make an instrument which even imperfectly embodies the principle of this scale, so we use an air or other thermometer, and adjust its corrected reading to give the 'absolute' temperature.

Now this is very closely parallel to the measurement of time. The air thermometer may be compared with my 'volume-clock': the unit of time is that in which unit volume of sand falls. If the dial does not record this, then its reading must be corrected. The corrected 'mass-clock' and 'number-clock' readings similarly correspond to the corrected mercury-in-glass and platinum resistance thermometer readings, and they may differ from each other and from the volume-clock reading. None of them necessarily shows the 'time' of physical theory, for that is indicated by the 'ideal' clock, which corresponds to the absolute thermometer.

This is commonplace knowledge with regard to temperature, but so far as I know, no one has hitherto pointed it out with regard to time—possibly because all time scales happen to be identical in a single co-ordinate system. Books on relativity usually say simply that a moving clock runs slow by a particular factor, leaving it to be inferred that anything that ticks and moves a pointer round a dial will visually display the Lorentz transformation. It was the purpose of my article to show by examples that this was incorrect, and to discover to what 'clock' the transformation formula applied.

Prof. Campbell maintains that in using a moving mass-clock the observer must move with the clock when measuring the mass but remain stationary when counting the grains. Why this difference? If he consistently moved with the clock he would obviously observe no effect of motion at all, but the action which Prof. Campbell prescribes for him seems a little arbitrary. I suspect that Prof. Campbell has not completely shed the idea of absolute motion; otherwise I cannot account for his allowing N and N' to differ. It is perhaps as well to point out again that, according to relativity, if an observer is initially at rest with respect to two identical instruments, and then one of them moves away from him, the 'change' in the indications of that instrument is exactly the same as if it were undisturbed and the observer, with the other instrument, moved with the same speed. Which is N and which N' in that case?

Finally, Prof. Campbell seems to me to be quite wrong in objecting to, say, my mass-clock measurements on the ground that "Without the Lorentz equations there would be no basis for making such measurements". You do not need the Lorentz equations in order to measure mass. The principles of mass measurement were defined before the Lorentz equations were thought of, and they are not to be changed because the observer decides to move while applying them.

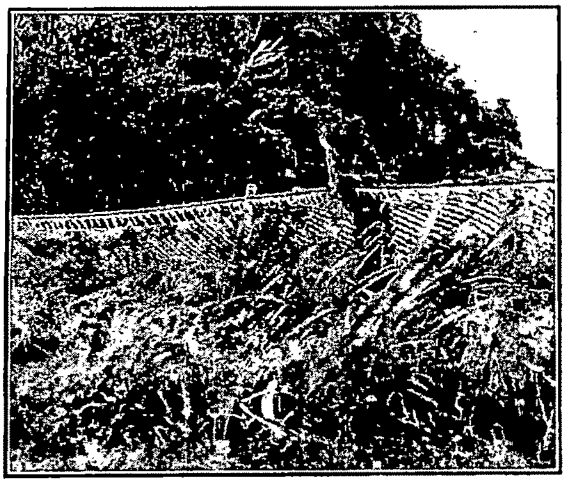
Unusual Ice Formation in Wiltshire

ON January 28 and 29, ice was formed in west Wiltshire under conditions unprecedented in the experience of local inhabitants: a record of the effects may have more than local interest.

January 27 had been a day of relative warmth and of heavy rain after a prolonged spell of frost and sunshine, and water collected over the frozen ground. The early morning of January 28 was also wet, there being a mild drizzle; but water was freezing under foot and the branches of trees crackled. By midday, though rain continued, ice had become a conspicuous feature of the landscape. Blades of grass were embedded in needle-like sheaths, the taller stems in glass-like rods, and dead flower heads had given rise to ice flowers of beauty and delicacy. On hedgerows and trees, on roads, stone walls and wire fences, the same process was at work. Everything, including threads of hair entangled on barbed wire, had become thickly coated; and trees acquired a fantastic appearance suggesting giant candelabra of crystal.



[Photo by O. W. Davies

By January 29 the ice had thickened. Grass blades were no longer encased in needles but in thick fingers of ice, and fields became most uncomfortable to walk over. Where grass stood high amid erect heads of dock, plantain, napweed, yarrow, etc., they had become a growth of brittle ice-bound stems. The weight of ice on trees and telegraph wires was now overwhelming and large boughs crashed to the ground.

Accurate measurements of the ice were not made. It was formed on the exposed and on the upper sides of supporting surfaces. In section, the fingers of ice were roughly elliptical, the original support occupying a position near the periphery in the longer axis. Around telegraph wires the ice was, however, circular (*circa* ¾ in. in diameter) which suggests the wires had undergone torsion. Icicles hung from some of the trees and from the eaves of buildings, but were not a conspicuous feature of the landscape.

Since the above was written a similar account of the same storm at Petersfield has been published by Cave[1]. Comparison of the two suggests that ice formation in Wiltshire started some twelve hours later but followed the same course. Storms of the kind are evidently rare though on record[2,3,4] and information is scanty on their causative factors, on the growth of the ice, and on its effects upon living vegetation. The report[5] that on March 5 New York experienced the worst ice-storm for 25 years is also of interest.

Witwatersrand Local Tremors

IN an article on "The Earthquake in Turkey"[1] Mr. E. Tillotson refers to the idea that violent earthquake shocks appear to be followed almost immediately by sympathetic shocks in various parts of the world. In this relation he points out that on the same day as that on which the earthquake occurred in Turkey, December 27, 1939, earthquakes occurred in San Salvador, Los Angeles, Tangier and "Between December 27 and 28, twenty-five earthquakes and earth tremors . . . shook the gold mining district of the Rand near Johannesburg in South Africa".

The reference to the Witwatersrand may be misleading without further knowledge of the conditions prevailing there. Earthquakes do not occur on the Witwatersrand, but local tremors are of frequent occurrence. These tremors were unknown before 1908; they began then to attract attention and their numbers increased very rapidly for some years and then more slowly. The frequency of their occurrence has kept pace closely with the increase of mining activity. A statistical study of the Witwatersrand local tremors covering a period of twenty-seven years has recently been undertaken by Dr. P. G. Gane of the Bernard Price Institute of Geophysical Research, Johannesburg[2].

Dr. Gane accepts the idea that the primary cause of these tremors is the local instability due to mining operations and has attempted to find 'trigger-forces' which might affect their actual occurrence. He concludes that blasting in the mines is likely to be by far the most effective trigger.

During the year 1939, 2927 local tremors were recorded by the seismograph at the Union Observatory, Johannesburg. Of this number, 286 were strong enough to be felt. There appears to be a tendency for the tremors to occur in groups. Such a group was experienced on December 27–28, but the occurrence of a large number of tremors in one day is not a particularly outstanding event, and should not be considered as having any bearing on the question of sympathetic earthquakes without further investigation.

Mutarotation of Gelatin

SUBSTANCES which exhibit optical activity in solution do so as a result of molecular dissymmetry, the most common cause of which is the presence of an asymmetric atom in the molecule. In the crystalline condition, optical activity may be exhibited by substances which do not contain dissymmetric molecules. In this case, the optical activity is due to a dissymmetric arrangement of the units which make up the crystal and disappears when the crystal is dissolved, because the structural dissymmetry is thus destroyed. Certain substances with dissymmetric molecules show a combination of these two effects, structural dissymmetry being superposed on the molecular dissymmetry in the crystalline condition.

These well-known facts have a bearing on the mutarotation of gelatin, that is, the change in optical rotatory power which is associated with the sol $\rightleftharpoons$ gel transformation. The optical activity of the sol is derived from the asymmetric carbon atoms of the protein molecules. In the gel, optical activity due to a dissymmetric arrangement of the protein molecules is superposed. The mutarotation therefore adds to the evidence that the protein molecules form an ordered, rather than a random, structure in the gel.

These views may have been implied by previous authors but they do not appear to have been explicitly stated.

Points from Foregoing Letters

FROM combined X-ray and chemical evidence, W. T. Astbury and Florence O. Bell put forward a model for the molecular structure of the fibres of the collagen group. The average length per amino-acid residue in the direction of the fibre axis is about 2·85 A., and the intramolecular pattern requires no fewer than 288 residues in a row. Owing to the high content of proline and hydroxyproline the polypeptide chains are partly in a *cis*-configuration, as opposed to the rather longer *trans*-configuration of the β-proteins.

Experiments are described by L. Meitner which give the capture cross-sections for thermal neutrons in thorium and lead. Using the thorium capture cross-section and the ratio of β-ray activities of ^{239}U and ^{233}Th (under identical experimental conditions) due to thermal neutrons, the capture cross-section for thermal neutrons in ^{238}U is obtained as well.

A new conception concerning the effect of substrate polarity on the velocity of enzymatic catalysis is pointed out by D. B. Taylor. Substrate polarity is suggested as a factor influencing enzyme specificity. The significance of substrate polarity is discussed.

S. H. Clarke and C. B. Pettifor find that the equilibrium moisture content, the shrinkage during drying, and the strength-density ratio in hardwood timbers are apparently dependent on the degree of lignification as revealed by histological reagents; moreover, the influence of the degree of lignification on strength is itself dependent on the moisture content of the wood.

Two carotinoid pigments, echinenone and γ-carotene, have been isolated from the red sponge *Hymeniacidon Sanguineum* by P. J. Drumm and W. F. O'Connor. The Crustacean pigment astacene, hitherto the only carotinoid isolated from a member of the Porifera, was not present.

R. A. R. Gresson finds that during fertilization the sperm middle-piece, and in some cases at least, the entire tail, is carried into the egg of the mouse. The mitochondria of the sheath of the axial filament become distributed through the ooplasm, and are presumably transmitted, in approximately equal numbers, to the first two blastomeres. There is evidence that the Golgi material of the sperm is also introduced into the egg; it undergoes fragmentation and becomes distributed through the cytoplasm.

G. W. Scott Blair and Miss F. M. V. Coppen find that direct subjective comparisons of 'firmness' can be made between elastic and fluid materials where the dimensions of 'firmness' vary by T^{-1}, but that a reversal of judgment is obtained over a wide range by varying the time of testing. The range is about the same whether the viscosity or the compression modulus is varied.

RESEARCH ITEMS

Ancient Gold-working Site in Rhodesia

A midden site on the Macardon Claims, West Nicolson, Gwanda District, Southern Rhodesia, discovered by Mrs. Winifred Macdonald and examined by her, produced material of no little interest which has been described by Neville Jones (*Trans. Rhodesia Sci. Assoc.*, 37; 1939). The size and thickness of the midden deposit suggest an occupation by one or two families for not more than fifty years. A flattish granite rock which outcrops on the surface is almost entirely covered by dolly-holes and was evidently used for the purpose of crushing the auriferous quartz mined in the vicinity. The crushing was done by means of pestles of diorite some of which were found still standing in the holes as the original inhabitants had left them. Most of the holes contained fragments of quartz broken to a size convenient for dollying. A little fine gold was obtained from the holes. Objects found included a portable crushing mortar, hammers, gold in the form of beads, cylindrical and tubular, foil, tacks, links, etc., twisted copper wire, copper chain fragments and links, copper beads and needle, objects of iron, including battle axes, imported celadon ware, beads and bored sea-shells (Polinices, Cypræa and Oliva), locally made ornaments of soapstone, beads of ivory, ostrich shell, achatina shell, amulets, pottery and a portion of a tuyère for ore reduction and slag. The gold beads are significant for methods of manufacture. From the evidence of the pottery, which is of the Sotho and Shona traditions, the celadon, the beads and the association of gold objects, it is probable that the Macardon site is to be dated at about the close of the fifteenth century.

The 'Ultra-Perceptive' Faculty

The existence of an 'ultra-perceptive' faculty, that is, the extension of perception beyond the normal and intellectual range, is not proved, but the scientific study of such perception has during the last few years received a fresh impetus. A paper by Dr. J. Hettinger, prepared for the Dundee meeting of the British Association, gives an account of an attempt to test statistically the probability of such a faculty. More than 150 subjects took part in the experiments which were carried out with the assistance of two professional 'sensitives'. Articles obtained from the subjects were placed in separate sealed envelopes and taken by the experimenter to the residence of the sensitives; one of the sensitives handled the envelopes while the other merely concentrated on the envelope laid on the table. The 'sensitive' then commented on the subject owning the particular article; for example, concentrating on one article, the sensitive said, "Pile of shillings, as if saved for some purpose". The subject with reference to this said, "I was counting the takings in a shop at the time, and had silver in piles." As a control, for each item given with regard to a particular subject by the sensitive an equal number of fictitious items was presented for acceptance or rejection. The results were treated to a detailed statistical analysis, and it was found that the deviation from chance expectation was more than fourteen times the probable error, indicating the probable existence of an ultra-perceptive faculty.

Age of Wild Birds of Prey

In a short paper E. Lowell Sumner, jun., gives the ages attained by representatives of a few species of raptorial birds which had been ringed by him during the past fifteen years (*Condor*, 42, 39; Jan. 1940). The greatest age was attained by a screech-owl, *Otus asio quercinus*, which was shot thirteen years after ringing, and the average age of five returns of this species was 5 years. A barn-owl, *Tyto alba pratincola*, lived for 10 years 4 months, and the average of eleven returns was 3 years 2 months; two horned owls, *Bubo virginianus pacificus*, almost equal in age, averaged 2 years 6 months. The diurnal birds of prey seem to have rather shorter spans. Of four recovered red-tail hawks, *Buteo borealis calurus*, the oldest had survived for 1 year 5 months, and the average was only 7¾ months. One Canadian golden eagle was captured at least 3 years 10 months old, and one sparrow-hawk, *Falco sparverius*, at 2 years 7 months. The numbers ringed and recovered in this experiment are too small to give a reliable indication of either average or maximum age, but the distances at which the birds were recovered suggest the relative tendency to wander. The four red-tails were captured at an average distance from the ringing place of 69 miles, the single golden eagle and sparrow-hawk respectively at 23 and 10 miles, the eleven barn-owls averaged 21 miles, as against one mile for the five screech-owls, whereas the single long-eared owl recaptured had travelled 49 miles.

Toxicity of Selenium-containing Plants to Pests

Among papers read before the annual meeting of the American Association for the Advancement of Science, which took place at Columbus (Ohio) at the end of December last are two on the above subject. V. H. Morris, C. R. Neiswander and J. D. Sayre discussed a method of rendering corn plants resistant to red spider attacks by growing them in nutrient solution to which was added each week 1 p.p.m. of sodium selenate. When the rate of selenium application was increased to 2 or 3 p.p.m., no red spiders were found to survive. Under such conditions the growth and normal nutrition of the plants was unaffected. Similar results have been obtained in additional tests with a number of other species of plants. In the second communication Messrs. Neiswander and Morris described results of experiments indicating that an accumulation of 90–100 parts per million of selenium in the tissues of certain plants was sufficient to prevent infestation by the common spider, *Tetranychus telarius*, and that a lesser amount controlled the chrysanthemum aphid *Macrosiphoniella sanborni*. The investigation suggests a possible method for controlling pests of ornamental plants.

Viruses and their Insect Vectors

The complex relations which exist between a plant virus and the insect which transmits it have been studied by M. A. Watson and F. M. Roberts (*Proc. Roy. Soc. Lond.*, B, 127, 543–576; 1939). They used three viruses, namely, potato virus '*Y*', cucumber virus 1 and Hyoscyamus virus 3, which cannot be transmitted mechanically and are non-persistent in the insects which transfer them. Three species of aphid were used as vectors: *Myzus persicæ*, *M. circumflexus* and *Macrosiphum gei*; their efficiency in transmitting the viruses increased with increasing time of fasting before feeding upon infected plants, and decreased as the time of feeding upon the diseased hosts increased. It would therefore appear that the viruses are inactivated by some substance produced by the aphids when feeding. *Myzus persicæ* was the most successful vector, but the efficiency of each aphid varied according to the concentration and localization of virus in the plant, and to the inhibitive capacity of the insect for the virus.

Erosion Surfaces in the Allegheny Plateau

AT the annual meeting of the American Association for the Advancement of Science, during December last, J. L. Rich presented an illuminating paper on the identification and interpretation of erosion surfaces. Aerial photographs of selected parts of the Allegheny plateau were used to illustrate the thesis that projected profiles or visual inspection of skyline elevations cannot be relied upon for the determination of the altitude of an erosion surface unless the region has not passed beyond the mature stage of the cycle of erosion. For all post-mature stages an indeterminate amount of elevation must have been lost by the inter-valley divides. Physiographic evidence proves an enormous difference in the rate of erosion between certain shale horizons in the Pennsylvanian and the massive Pottsville conglomeratic sandstone at its base. The difference is such that two or more cycles can be brought to old age stage on the shales, while the first cycle has scarcely passed infancy on the sandstone. In view of these complications, due to rock resistance and its bearing on the stage reached in the erosion cycle, it is clear that a re-examination of the physiography of the plateau is called for.

Decomposition of Azomethane

THE decomposition of azomethane yields different products depending on the procedure employed. Emmett and Harkness (*J. Amer. Chem. Soc.*, 54, 538; 1932) found that catalytic decomposition using an iron (synthetic ammonia) catalyst gave methylamine as an intermediate product and ammonia, hydrogen and carbon as principal end products, while Taylor and Jahn (*J. Chem. Phys.*, 7, 470; 1939) found that pyrolysis and photolysis gave initially methyl radicals which added on to azomethane molecules forming tetramethylhydrazine, which afterwards decomposed. Recently, Henkin and H. A. Taylor have reported data (*ibid.*, 8, 1; 1940) on the decomposition of azomethane by atomic hydrogen at 27°, 110°, and 195°. At 27°, gaseous products were absent. A liquid product, obtained in a liquid nitrogen trap, contained a small fraction volatile at −78°, which was probably unchanged azomethane. The non-volatile liquid component, which was, therefore, presumably the sole product of the reaction, was colourless, basic, and a good reducing reagent. It gave the azo-cuprous chloride complex characteristic of a secondary hydrazine, and microanalysis of the picrate and oxalate showed it to be *s*-dimethylhydrazine. The absence of hydrocarbons indicates the non-rupture of the azomethane molecule. At 110°, methane and ethane were present (10 : 1). A considerable proportion of the liquid product was volatile at −78°, and combustion tests on the gas indicated methylamine. The residual liquid was again dimethylhydrazine. The liquid product from the 195° decomposition contained a larger amount of methylamine; the ethane yield was almost zero, and the amount of methane was only 20 per cent of that at 110°. Analysis of the fraction non-volatile at −78° indicated a compound with a nitrogen content lower than dimethylhydrazine. This is explained by assuming that methyl radicals join to azomethane molecules, with the ultimate production of tetramethylhydrazine and trimethylhydrazine. The possible mechanisms involved at the different temperatures are discussed.

Diffraction of Protons by Vapours

DETERMINATION of molecular structure by electron diffraction is now a well-established method. Provided that a suitable source and technique could be developed, the diffraction of protons by vapours is an extension of this method of great potentiality, since the intensity of scattering of protons by an atom should be about 2,000 times greater than the scattering of electrons. Light molecules could then be investigated. A first attempt in this direction is reported by H. J. Yearian (*J. Chem. Phys.*, 8, 24; 1940), who describes an apparatus and preliminary results on carbon tetrachloride which agree satisfactorily with electron diffraction data. An arc of 0·5–2·0 amp. is struck in hydrogen in a stainless steel ion source and the ions are accelerated to 1·5–2·0 kv. The beam (approximate composition, 20 per cent H_1^+, 50 per cent H_2^+, 20 per cent H_3^+, 10 per cent heavy ions) is resolved into its ionic constituents by a magnetic field and the selected beam, after suitable focusing, falls on a stream of vapour at 10^{-5} mm. pressure. The scattering is recorded photographically. Many difficulties of technique were encountered, principally space charge effects near the ion source, neutralization of the beam by molecules of the vapour, loss of sensitivity of the photographic film due to outgassing. Precautions taken to minimize these and other difficulties are discussed. The experience gained in these preliminary experiments has indicated certain desirable modifications of technique, which are outlined. This investigation may well be the precursor of an important new method of elucidating the structure of molecules.

Age of a Meteorite

A SHOWER of fragments of a stony meteorite which fell in Putulsk (Poland) in 1868 were supposed, on account of the reported high heliocentric velocity, to be extra-solar material, although this result is not confirmed by recent recalculation (C. C. Wylie, *Science*, 9, 264; 1939). The protactinium contents of this meteorite and of a granite low in radioactive material as representative of terrestrial material of similar composition have been determined by W. C. Schumb, R. D. Evans and J. L. Hastings (*J. Amer. Chem. Soc.*, 61, 3451; 1939) and the protactinium/radium weight ratios found. From the results the conclusion is reached that within the limits of error the age of the uranium atoms in this specimen of the Putulsk meteorite is the same as for terrestrial uranium. The protactinium was determined by co-precipitation with zirconium phosphate, followed by purification of the ignited pyrophosphate, the alpha-ray activity being measured on a recording alpha-ray counter. The method will determine as little as 10^{-13} gm. of palladium per gm. of siliceous material.

SEA FISHERIES OF EUROPE

ONE of the most valuable as well as the most generally interesting of the various publications of the Conseil Pérmanent International pour l'Éxploration de la Mer is its *Statistical Bulletin*, in which are tabulated extensive and detailed statistics relating to the sea fisheries of the maritime countries of northern and western Europe. Even in normal times, such ample and diverse data require much time and labour to assemble and work up. But in the recent years of economic instability and wildly fluctuating currency values the difficulties of such work have very greatly increased. Nevertheless, by the diligence and resourcefulness of the editor and his staff, they have all been heroically met and successfully overcome, and volume 27, presenting the data for the year 1937, has recently been published*. In order to facilitate interpretation of the mass of detailed tables, a very comprehensive and extremely lucid summary of the main conclusions to be drawn from them is given—as in previous years.

The total quantity of fish landed in 1937 from all the sea fisheries of northern and western Europe (omitting Russia but including Iceland and Faroe) was more by about 4 per cent than in the preceding year; but for the nine principal countries the gain over the preceding year was no more than 2 per cent. For these nine countries the total landings were 32 per cent above the total landings in 1913, the last year prior to the War of 1914–18, which has long been used as a standard of comparison. (Table 1.)

From the British point of view the most comforting information contained in the *Bulletin* is that England, after many unsatisfactory years, at last showed an appreciable increase in landings with a rise of 7 per cent in the total catch in 1937 over 1936. But by far the largest increase was shown by Iceland with 27 per cent increase, followed by Holland with 15 per cent and Germany with 11 per cent. Both the German and English increases are shown to be due in large measure to the opening up of the Arctic trawl fishery at Bear Island and Spitsbergen.

TABLE 1.

TOTAL QUANTITY OF FISH LANDED (IN '000,000 KILOS OR 1,000 TONS) AND PERCENTAGE-RATIO TO 1913.

	Total quantity				Ratio to 1913			
	1913	1935	1936	1937	1913	1935	1936	1937
England	820·5	729·9	804·0	865·4	100	89	98	105
Norway	731·5	1036·6	1146·9	1035·2	100	141	157	142

[1] Estimate based on wholesale price-index from year to year in accordance with the principles adopted by Nellemose in *Rapp. et Proc.-Verb.*, **98**. "A Review of Fishery Statistics in Relation to Wholesale-Index".

[2] Eire and Northern Ireland.

[3] Reduction too great; cost-of-living index used in lieu of wholesale index.

Concerning Scotland, however, the all too dismal tale, continued over many years, has once again to be told. For more than ten years previous to 1937 the Scottish landings had been diminishing and in that year they had fallen to less than two thirds (60 per cent) of those of 1913, and were 7 per cent less than those of 1936. Only two other countries showed diminished landings in 1937 as compared with 1936—Norway by a little and Belgium by about 5 per cent. Nevertheless, both these countries landed much more fish than in 1913—the former 1½ times and the latter 2½ times the 1913 total.

The most outstanding changes in the share of the total catch taken by each of the principal countries were shown by the British and German landings. Once more comparing 1913 with 1937, it is found that the combined shares of England, Scotland and Ireland had fallen from 45 per cent to 28·5 per cent, while Germany's share had risen from 6·5 per cent to 16·2 per cent of the whole.

In spite of formidable difficulties in ascertaining, computing, and comparing the values of the catches in the different countries, and the still greater difficulty of finding a basis of comparison with the values of former years, the attempt has been made and careful estimates based on price indexes, are presented. This done and the price of fish adjusted to the general price index, the surprising fact emerges that the value of fish per kilo, at least until 1936, appears to have changed very little since before the War of 1914–18; that is, whatever the apparent changes in market prices may have been, the *relative* price of fish remained much as before. Germany and Holland, however, were an exception, for in those countries the adjusted fish prices were much lower in 1936 than in immediately preceding years and notably lower than in 1913, probably because in these two countries the markets were better supplied than formerly and fish had become a more plentiful and cheaper food.

---

* *Bulletin Statistique des Pêches Maritimes des Pays du Nord et de l'Ouest de l'Europe.* Rédégé par Sir D'Arcy Wentworth Thompson. Vol. 27 (pour l'Année, 1937). København: Andr. Fred. Høst and Fils). Kr. 3.00.

A still more curious and surprising thing is that the adjusted prices of 1937, as compared with those of 1913, were lower in all countries except Scotland, Ireland, and Denmark. In the first two countries fish prices appeared to remain considerably above the 1913 level; and in Denmark, although decreased by about 20 per cent in two years, they still remained above the pre-War level. In all other countries, and most notably in Germany and Holland, fish appears to have been considerably cheaper in 1937 than in 1913. In Table 2, where the prices in recent years are given and also their percentage ratio of the 1913 values, the all but universal reduction in fish prices between 1935 and 1937 is very conspicuous. No explanation of this very remarkable fact is attempted.

From these and many other equally interesting general considerations, the *Bulletin* proceeds to give more specialized information concerning such matters as the landings of different fishes, and groups of fishes, from the numerous fishing grounds; the shares of the various participating countries in these landings; and even the seasonal fluctuations in the mean monthly landings of certain fishes of special importance, for example, plaice and sole, from the North Sea and elsewhere.

For all those with any interest in fish or fisheries, whether from the scientific or commercial point of view, the *Statistical Bulletin* is a mine of useful information most attractively presented. Not least among the many harmful results of the present War will be yet another interruption in the continuity of much of the data upon which the *Bulletin* is based.

AERIAL, GEOLOGICAL AND GEOPHYSICAL SURVEY OF NORTHERN AUSTRALIA

BY DR. L. DUDLEY STAMP

FOR roughly a century the development of tropical Australia proceeded in an atmosphere of unqualified optimism. It was almost universally believed that only capital and enterprise were needed to render richly productive of minerals and agricultural wealth the vast untenanted northern half of the continent. Agricultural successes on the well-watered coast of Queensland were used to discount a dismal succession of failures elsewhere, and a few highly successful mining enterprises caused a willing public to forget many failures. Within the last fifteen years a professor in an Australian university who dared suggest that tropical Australia was far from being an El Dorado and in any event could only be developed by permitting coloured immigrants was so pilloried by the Press that he sought refuge in resignation. But the negligible return for a huge expenditure of public money at last rendered inevitable the conclusion that all was not well, and the long reign of optimism was succeeded by a period of extreme pessimism.

In the last few years has come the realization that the whole problem of tropical Australia needs to be examined scientifically and without prejudice, using all the weapons at the command of the modern investigator. In that spirit the three Governments concerned—the Governments of the Commonwealth, Queensland and Western Australia—agreed to inaugurate a survey with the object of seeking new mineral resources in the parts of the continent lying north of 22° S. £150,000 was provided—half by the Commonwealth Government, a quarter each by the other two—and it was intended originally to devote three years to the work. It was the first time in the history of Australia that three Governments had pooled their resources for such an investigation. On September 19, 1934, a party of four (Mr. P. B. Nye, executive officer of the Survey, Mr. L. C. Ball, Queensland, Mr. F. G. Forman, Western Australia, and Dr. W. G. Woolnough, Commonwealth geological adviser) set out on a preliminary reconnaissance flight of 12,000 miles to determine areas suitable for investigation. It was agreed that out of more than a million square miles approximately some 10,000 square miles could reasonably be covered in three years, the survey being confined to metallic minerals, particularly gold. Survey work actually began in May 1935 and falls into three parts. Aerial photography was carried out by the Royal Australian Air Force; ground surveys by three parties (in Queensland, Northern Territory and Western Australia respectively); geophysical surveys in selected areas were at first carried out under contract by the Electrical Prospecting Company of Sweden (Mr. Sepp Horvath) and later by the Survey staff itself.

The Survey has issued comprehensive progress reports every six months, beginning with a combined one for the whole period ended December 31, 1935. Those for the periods ended December 1935, 1936 and 1937 are particularly valuable as general summaries, and in the last it was pointed out that the work was far from complete and that it was to be continued during 1938. The detailed results are contained in the individual reports, of which there are thirty-nine for Western Australia, thirty-seven for the Northern Territory and thirty-five for Queensland, though all are not yet published. These 111 reports follow a uniform plan: all are issued by the Government Printer, Canberra, they are in foolscap size with appropriate maps, and set out the facts, favourable or unfavourable, on which private enterprise may assess the possibilities. Many are short—a page or two of text—and naturally most deal with ore fields previously known.

A particularly interesting report is Queensland No. 9—on the Croydon-Golden Gate area which was formerly one of the chief gold producers of Queensland and yielded £3,000,000 worth of gold before being closed down some years ago. It was hoped that geophysical methods would lead to the discovery of new reefs beneath the cover of Cretaceous sandstones, laterite and alluvium. The methods used—electromagnetic, self-potential, magnetic—are described, and here the electromagnetic was found most successful and disclosed numerous good conductors considered to arise from reef-channels at depths corresponding approximately to water-level. The Survey was empowered to carry out shallow tests but not drilling, and so further work is left to private enterprise.

Report No. 17 of the Northern Territory on the Fletcher's Gully Area, Daly River, may be selected as illustrating a type of history all too common. Traces of gold were discovered in 1905 in almost uninhabited country 100 miles south of Darwin. A 'gold rush' of about thirty miners followed, but in three months only two remained—working stream tin—and the claims were soon abandoned. In 1909 a group of Chinese got 183 ounces of gold by steady work, but in 1910 the area was declared a 'goldfield' and the Chinese had to leave. The field was again abandoned after a few months. In 1912 the Chinese returned. In 1918 a new serious start was made by erecting a battery, but it apparently was never used. In 1926–29 there was a little spasmodic working by a few old Chinese. Now the Survey discloses small sub-horizontal reefs, some possibly with payable values, but does not encourage further work.

In some reports comes the thrill of new discoveries. Queensland No. 12 deals with an area in Cape York Peninsula, proclaimed a goldfield in October 1936 and surveyed in the following months. Even there the old type of prospector had penetrated so long ago as 1878 and may have assessed the true value of a mineral field, which now promises to be more important for its iron ore.

It is impossible, in the course of a brief review, to do more than indicate the existence of these valuable reports and to congratulate all concerned on the solid work they have carried out—especially Sir Herbert Gepp, the director, Messrs. Ball, Forman and Pye, his executive committee, and Messrs. C. S. Honman, P. S. Hossfeld, K. J. Finucane, R. F. Thyer, E. L. Blazey and their assistants, of the field staff.

BROADCASTING OVER WIRES

THE idea of conveying speech and music programmes over a wire network is by no means new in Great Britain, for so early as 1895, the Electrophone Company provided a service to telephone subscribers by special connexion to theatres, music halls and churches. Until a few years ago, however, no serious development had taken place owing to the indifferent quality of the service, the absence of suitable loud speakers and amplifying equipment, and the lack of public demand resulting from the relatively high cost involved. The introduction and success of radio broadcasting, accompanied by revolutionary developments in technique and equipment, have caused renewed attention to be given to the possibilities of diffusing programmes over wire networks. For some years past a number of relay companies have been re-distributing the ordinary broadcast programmes over special wire network systems to subscribers who prefer this mode of reception to that involving the use of a normal receiver.

On March 30, 1939, the Postmaster-General announced that the Post Office was contemplating the introduction of a system of distributing broadcasting programmes over the line telephone network, as a service additional to that of the existing relay companies (see NATURE, April 8, 1939, p. 592). In a paper read before the Wireless Section of the Institution of Electrical Engineers on March 7, Dr. T. Walmsley gave an account of the technical progress made in this subject up to the outbreak of the War, by the Wire Broadcasting Branch of the General Post Office. After referring to the fact that the wire broadcasting system is likely to be relatively free from the various types of interference to which radio broadcasting is subject, the paper presented a detailed consideration of both the principles and the technique involved in distributing over wires at either audio or radio frequencies.

While the audio frequency system of distribution could make use of existing telephone lines, considerable interference with other telephone circuits would result if the electrical energy were transmitted over the lines at a sufficient level to operate loud-speakers direct. Thus either the energy level must be reduced and an amplifier used on the listener's premises, or a special wire network must be employed. The latter system is the more satisfactory and has been more widely used up to date. Two arrangements of the scheme are possible; the first provides a separate pair of wires for each programme from the distribution station to a selector switch at the listener's premises; while the second provides several programmes over one pair of wires to the listener, who, by means of a special switch, is enabled by remote control to select one of several programmes available at the distribution station. Which of the two is the more suitable depends largely upon local conditions, the geographical distribution of the subscribers, and the relative costs of the switching systems and the installation of the necessary lines. The remote switching system has many interesting technical features, which are fully described in the paper.

The chief attraction of the distribution systems involving carrier or radio frequencies lies in the fact that the existing electricity supply or telephone networks may be utilized, with a consequent saving in line plant costs. The fact that the electricity supply networks in Great Britain are connected to a larger number of premises than the telephone network constitutes the chief advantage of their utilization for distribution of programmes at carrier frequencies. This advantage has, however, limitations set by technical problems such as insulation, so more attention has been given to the use of telephone lines for this purpose. By choosing the carrier frequencies to be within the normal radio broadcasting band, the subscriber can conveniently use a normal commercial broadcasting receiver, the various programmes available over the telephone system being selected by tuning the receiver to certain assigned radio frequencies. The switch at the listener's premises is naturally provided with a change-over position in which the receiver is connected to a suitable aerial for reception of other broadcast programmes in the usual manner.

Dr. Walmsley's paper described the technical development of the equipment which has resulted in this method being placed on a satisfactory and practical basis. The reading of the paper was accompanied by a demonstration of the reception of both normal broadcasting and of special programmes over the standard Post Office telephone lines, using both the audio and radio frequency methods described. In the latter case, the reception is unimpaired by the use of the subscriber's telephone for a call and conversation in the usual manner. R. L. S-R.

RITUAL IN TIKOPIA OF THE SOLOMONS*

IN the first volume of his account of the ritual cycle known as "The Work of the Gods" in Tikopia, an isolated community in the British Solomon Islands Protectorate, Prof. Raymond Firth has confined himself mainly to giving an ethnographical account, reserving for later publication the major part of theoretical interpretation. In his introductory remarks, however, after pointing out that this, the most spectacular of his discoveries, had been mentioned only by the Rev. H. J. Durrad and Dr. H. R. Rivers without any hint that they were anything more than isolated performances, he goes on to indicate its basic significance for the understanding of Tikopia, while its analogies with rites in Hawaii and Tonga suggest interpretations of these latter, which cannot be inferred from the existing fragmentary and obscure accounts.

The rites fall into several main divisions: a symbolic set to initiate the cycle; a resacralization of canoes; a reconsecration of temples; a series of harvest and planting rites for the rain; a sacred dance festival; several memorial rites and the rites of vanished temples; and in the trade wind season, the ritual manufacture of turmeric. The rites are one of the most elaborate expressions of the system of rank and of the religious beliefs of the people; it has important economic aspects, is related to the institution of marriage, sets the formal seal on fundamental forms of recreation, and provides sanctions for many of the most basic values.

The concrete title "The Work of the Gods" embodies two concepts: first that of a religious sanction, and secondly that of the ritual as a series of obligations involving the expenditure of goods and time. The religious sanction lies in the fact that the ritual cycle is believed to have been instituted primarily by one deity, the principal god of Kafika, who at the same time is worshipped by the chiefs of the other three clans; but into the scheme are drawn also other gods and chiefly ancestors. There is no elaborate mythology to explain how the ritual cycle came into being. There is a strong reverence for the ritual and the sacred objects connected with it.

The important matter of fixing the exact day on which the rites shall begin throws a significant light on the calendrical system and astronomical knowledge of Tikopia. The people have no fixed calendar and no names for the months or for the days or nights of the month. They count moons or nights of the moon for specific purposes, as in estimating pregnancy or periods between events. The term *tau*, meaning a 'measurement' or 'count', is used for a season, or sometimes a year as a whole, but without precision. Sometimes a *tau* has six months, sometimes seven. It is a seasonal period rather than a calendar period and refers primarily to the most marked climatic phenomenon in the island, namely, the alternation of the trade wind with the monsoon season. The seasonal changes, which are accompanied by changes in economic pursuits such as fishing, are the main basis for the seasonal ritual, as shown by the terms "The Work of the Trade Wind" and "The Work of the Monsoon". The trade wind begins to blow at about April and dies down in October, when the monsoon season begins.

Although the main index for the beginning is thus given by seasonal change, it is correlated with and corroborated by other factors. Though the Tikopia have no sidereal calendar, they use astronomical observation to a certain extent in time reckoning. Thus when the Pleiades rise, "the ocean has begun to bite", that is, the fish rise and are plentiful. It was said that when the Pleiades appeared above the sea in the east at dawn, it was the signal for the work of the trade wind to begin. At this time Taro, another star, stood high up at dawn. The work of the monsoon is also so guided. When Manu, a bright star, has passed the zenith in the evening, it is time to throw the firestick, for the season's work has arrived. Saraporu, another prominent star, stands midway in the western heavens in the evening at this time, but towards the end of the festival, when the dance festival begins, Saraporu has gone below the horizon. Tokens of the approach of the work of the monsoon season are also given by the migrations of birds and changes in vegetation.

The order of the rites of the Work of the Gods is traditionally fixed, though the space between them to some extent is at the discretion of the Ariki Kafika. But any ordinary Tikopia knows the sequence, and the full cycle in the traditional form shows that any man, not responsible for the organization of the rites, can carry in his memory a sequence of more than thirty days.

The Christianization of the Ariki Kafika, who took precedence over the other three chiefs in the rites, has brought about certain changes and adjustments. In the course of generations, such variation may become part of the traditionally accepted practice. This with the conseveration of other variations and causes of variation suggests the reflexion that "Polynesian culture must not be regarded as a static arrangement resting upon an original fusion of diverse elements, but as a dynamic arrangement with a tendency to variation perceptible in each generation, and with a selective process by which some at least of these variations are built into the cultural system".

SEVENTY YEARS AGO

NATURE, vol. 1, March 17, 1870

The Geological Calculus

In a letter under this title, [Sir] W. Boyd Dawkins, F.R.S., discusses the recent articles by Alfred Russel Wallace on the measurement of geological time. He concludes :

"But can we measure geological time by the lapse of years ? If so, we shall have solved a problem infinitely harder than that which has foiled the archæologists. Can they fix the date, say of the introduction of iron into Europe, or of the dawn of the age of bronze or of stone ? No man would venture to answer yes. . . ." If, then, we are ignorant of the dates of, say, the kings of Assyria, "which are, comparatively speaking, of yesterday, and we can simply tell that one succeeded another in a definite order, how can we reasonably expect to fix the date of any one period of the geological past ? . . . the geological 'when' merely implies before and after, while in history the idea not only of sequence, but of the lapse of how long before and how long after, can be mastered. The attempt to fathom the geological past with our short historical sounding line has up to the present time resulted merely in estimates, varying according to the assumed basis in each by thousands of centuries, that have been about as valuable in geological theory as Archbishop Usher's chronology has been found in Biblical criticism".

Sunday Lectures

A lecture delivered by Prof. T. H. Huxley in St. George's Hall, London, on Sunday, March 13, entitled "The Forefathers of the English People", is printed in full. Commenting on the occasion, a "note" reads :

"It is surely a sign of the times that we should be able to lay before our readers a scientific lecture delivered on a Sunday before a great audience, composed chiefly of the middle classes. The history—the all too short history—of English Sunday lectures is very curious and, withal, instructive. Some years ago the movement was commenced by lectures in St. Martin's Hall, which lectures, thanks to the activity displayed by 'The Lord's Day Observance Society', were brought to a close somewhat suddenly. They were afterwards revived (such is the perfection of our English law) with impunity, by the simple process of enrolling the lecturers and their friends as a religious body !" Eventually, two movements arose, the Sunday Lecture Society, and another, "emphatically the working men's movement, in which the exact programme which was at first threatened with prosecution is reproduced. Both these movements have been in operation, and have been the means of doing much good for some time past ; and no attempt has been made to interfere with that 'Free Sunday' which is of a good deal more importance to the working men of this country than even a 'Free Breakfast-table'. Surely one of those quiet victories by which each step in the march of real progress has been made good in English history has been won".

Hereditary Genius

Alfred Russel Wallace reviews at length Galton's "Hereditary Genius, an Inquiry into its Laws and Consequences". "In this book Mr. Galton proposes to show that a man's natural abilities are derived by inheritance, under exactly the same limitations as are the form and physical features of the whole organic world. Many who read it without the care and attention it requires and deserves, will admit that it is ingenious, but declare that the question is incapable of proof. Such a verdict will, however, by no means do justice to Mr. Galton's argument . . . his book will take rank as an important and valuable addition to the science of human nature".

A National History Society has just been formed at Winchester College. There is every reason to expect that the society will prove a lasting benefit to the college.

We are glad to see that meetings are being held in support of M. W. S. Allen's motion in the House of Commons to open museums on week-day evenings. We know of no argument against the experiment, and we believe the experiment would be an entirely successful one.

The Vicar of Cushendun, County Antrim, communicates the following to *Science Gossip* : "The following incident was told me the other day by a resident, who vouches for the truth of it, and which happened close to his residence in Cushendun, County Antrim. A rat, nearly white with age, and blind, was frequently seen led to the water by a young rat by means of a straw, of which the old rat held one end and the young rat the other".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned :

Assistant Executive Engineers in the Punjab Service of Engineers, Class I—The High Commissioner for India, General Department, India House, Aldwych, W.C.2 (quoting Appointment 1/4A) (March 23).

Assistant Officers (Civil Engineers) in the Indian Railway Service of Engineers—The High Commissioner for India, General Department, India House, Aldwych, W.C.2 (quoting Appointment 275/1A) (March 23).

Director of Education—The Director of Education, Education Department, Newarke Street, Leicester (March 27).

Superintendent of Technical Classes under the Government of Trinidad—The Secretary (IPR/CA), Board of Education, Kingsway, W.C.2 (March 27).

Second Assistant Bacteriologist and Pathologist—The Clerk to the County Council, County Buildings, Stafford (March 28).

Vice-Principal—The Principal, Bergman Osterberg Physical Training College, Dartford (March 29).

Director of Research—The Secretary, Research Association of British Rubber Manufacturers, 105–107 Lansdowne Road, Croydon (April 6).

Education Officer—The Clerk to the London County Council, The County Hall, Westminster Bridge, S.E.1 (April 15).

Assistant Lecturer in Geography—The Registrar, The University, Manchester 13 (May 1).

METHODS AND AIMS IN AMERICAN ARCHÆOLOGY

ALTHOUGH archæologists in the United States welcomed the financial assistance afforded field research and excavation by the measures taken by the Federal and State Government authorities for the relief of unemployment, their satisfaction was tempered by some misgiving. It is true that it now became possible to open up sites long marked as desirable for investigation, but of which the examination had to be postponed while the funds available were devoted to purposes of more insistent urgency in their bearing upon major archæological problems. At the same time, it was recalled to how great an extent the antiquities of the remarkable and unique indigenous civilization of the Americas had suffered from amateur and untrained trophy hunting. Further, public works were being inaugurated or accelerated which would add to the destruction on a vastly extended scale. The construction of a great dam in the Tennessee Valley during the War of 1914–18, for example, had inundated twenty-three square miles of country, and to this the projected scheme of the Tennessee Valley Authority would add a further 100 square miles, both tracts taken from a territory thickly studded with relics of Indian occupation, of which so considerable a proportion would now be lost for ever to archæological study. It was evident that there was an urgent call both for trained and skilled supervisors of excavations and public works, and for a scheme of conservation to preserve as much as was possible of the evidence of antiquity for study by posterity.

As an outcome of this apprehension, the matter was taken in hand by the National Research Council. In April 1939, the Division of Anthropology and Psychology of that body appointed a committee to study the needs of American archæology. This committee was composed of some of the most active among practising archæologists of the United States; among them were Dr. A. D. Strong, who acts as chairman, Dr. Clark Wissler, Dr. A. V. Kidder, Prof. Fay Cooper Cole, and Dr. W. S. Webb. The Committee has already published a report of a preliminary nature, of which an analysis by Dr. Carl E. Gutha, chairman of the Division of Social Sciences of the National Research Council, appeared in *Science* of December 8, 1939.

It has been pointed out recently that in the study of the indigenous civilization of the Americas, but more especially of the northern half of the continent, the distinction in method and outlook between archæological studies and ethnography and ethnology is by no means so strongly marked as it is, as a rule, in the study of Old World civilizations. On one hand, archæological methods and arguments more and more have to be applied to the reconstruction of an Indian cultural complex, while on the other hand interpretation of archæological data may be illumined by reference to the evidence of ethnography recording traditional Indian custom and belief, a source of which perhaps the fullest use has not always been made. Why Americanist studies should be peculiarly favoured in this way must be obvious. For one thing, American civilization, when once the tide of early immigrant peoples ceased to flow, remained virtually free from serious outside cultural and racial influence for some centuries—or at least so those of us would believe who are not diffusionists—until the impact of European civilization, at first of the Norsemen, though this is virtually negligible, and afterwards of other European peoples in the late fifteenth and sixteenth centuries. Further, and partly as a consequence of this prolonged isolation, American civilization shows a remarkable continuity of development, as well as a stability of condition, which has affected not merely the indigenous population but also the development of white civilization, a fact which writers on American civilization in its broader aspect have perhaps sometimes failed adequately to stress.

If we ignore the industrial zone and areas of mineral exploitation, American civilization is still based on agriculture and animal exploitation, though it is true that the place of the hunter and the bison is taken by the cowboy and vast flocks and herds of domesticated animals. Even though corn now grows in the plains where the bison once was hunted, this implies no break in the cycle of cultural development, for even as the agriculturist in the Old World has displaced the hunter, so in America the farmer has edged the herdsman off the lands which generations of wild cattle had fertilized for his crops of corn. The readiness of the early settlers and pioneers to adopt elements from indigenous culture, many of which survive to this day, bears testimony to the influence of the continental environment in moulding the technique of living from day to day.

It is evident that some such conception of the function of archæology in Americanist studies, as illustrative of a continuous development, was present in the collective mind of the Committee in deciding on the scope and in framing the terms of the preliminary report. The sphere of interest of that report, it was felt, was best limited to "an analysis of the principles which govern the methods and procedures of American archæological research" and could most usefully indicate its basic needs.

As herein formulated, the aim of American archæology is said to be "to make the past live again ; to preserve for posterity the story of the rise and spread of early cultures on the American continent and their influence on white settlement". From such studies, it is pointed out, much may be learned, not only in the field of human history, but also of such significant subjects as long-continued land utilization, cycles of climatic change and the history of important agricultural crops. It is interesting to note the implicit recognition of the fact that, given continuity of environmental and climatic conditions, an academic problem in archæology may have a practical bearing on the affairs of even such a progressive modern community as is found in contemporary American civilization.

The Committee recognizes fully that much excellent work has already been done and experience gained, as well as much valuable information gathered, through the assistance granted by Federal and State schemes for the relief of unemployment or in rescuing prehistoric records in districts about to be flooded. Yet in view of the fact that these relief projects are to be continued, and others are contemplated, it has been thought urgent that a statement should be issued at the earliest possible moment, giving the minimum requirements with which future work, whether public or private, should comply, in order to attain a standard of scientific accuracy satisfactory for the needs of archæological studies. In view of the stress laid upon general principles of archæological research and conservation, this document is of more than merely local interest.

In framing its statement of these requirements, the aim of the Committee has been to eliminate anything and everything in the nature of haphazard excavation. With this in view, it has covered every stage of the research in broad outline from its initiation, concerning which it is laid down that "a definite need should be shown for the solution of a well-defined archæological problem or for the conservation of prehistoric material placed in jeopardy by public works or other agencies, whether natural or human", down to final publication of a report which, it is insisted, should be as speedy as possible after the completion of the investigation. In regard to this latter point, however, it is emphasized that archæological investigation and 'hustle' have no affinities.

The Committee has laid down in some detail the organization for which a scientific institution or learned society must be prepared to provide when undertaking the responsibility for a research project under any one of the schemes fathered by Government authority. That responsibility cannot be regarded as ceasing with the provision of skilled archæological supervision. To this must be added the field staff, with academic training and field experience, competent to keep proper records in addition to carrying out the practical work of surveying, excavating or conducting the technical work of the laboratory, with, be it said, the complete equipment of technical apparatus, cameras, surveying instruments and the like, which each department of this work demands. A somewhat higher degree of specialization in function is power, leadership must be a question of good education and careful selection. To engage in politics in modern life and in a democracy without very hard intellectual work, great erudition and high comprehension of all divisions of science is impossible.

Scientific workers will welcome this emphasis on the importance of scientific training for those entering on political and administrative careers, but they should note also that Dr. Beneš is careful to point out that leadership demands something more than a man of analytical or reasoning capacity or scientific knowledge. Beyond intellectual ability, leadership involves decision and courage. Scientific learning or culture must be combined with keen intuition, and the capacity for rapid decision and action and for physical and moral courage.

On such leadership Dr. Beneš rests his hopes of dealing with the practical problems which democratic States must face in the immediate future: the reinforcement and consolidation of the executive power, and the development of new functions of the State; the establishment of better harmony and equilibrium between the judicial, legislative and executive organs in democratic rule; the redress of the weakness and deficiencies of the party and voting system, and the problems of nationalism and social reform. Such leadership alone will be equal to the establishment of a real and effective collective security and of a League of Nations which will afford the opportunity for such developments.

(2) "For Democracy" is a collective work. Its scope is wider in some ways than that of Dr. Beneš's book, for the first part of the book traces the development of democracy from the experience of Greece and Rome. If it has less to say about the League of Nations, like Dr. Beneš's book it includes an excellent short account of the modern totalitarian State and its dangers to freedom. Dr. Luigi Sturzo, the former leader of the Italian Popular Party, contributes a notable essay on democracy, authority and liberty, and this, with his concluding essay, on the future of democracy, is what scientific workers may find of most immediate appeal in the volume, though the significance of the deep-seated sense of unity pervading these writers—three French, two Italian, one German and one Spanish—revealed in these studies of democratic ideas and institutions seen through Catholic democratic eyes as a factor in movements towards the development of a United States of Europe should not be overlooked.

To Dr. Sturzo the spirit of democracy is freedom actuated in social life as correlative to authority, an authority in which the whole people shares, according to the capacities and position of each, in co-operation for the common good. It is in such a system that intellectual activities such as science can find their natural freedom of development, for that freedom which lies at the basis of democracy is also the life-blood of science. The main task in the defence of democracy to-day is the defence of freedom, and the defence of freedom is at the same time the defence of authority and of the social order.

In this defence Dr. Sturzo lays the main emphasis on education, involving not merely culture and training in the exercise or practice of political life but also in moral values. Intellectual or technical education alone offers no safeguards against the fanaticisms of the age, such as anti-Semitism. In this insistence on permanent moral values worthy of men and in harmony with the principles of Christianity, the book adds one more to the many which, like Middleton Murry's "The Defence of Democracy" or "The Price of Leadership", are stressing the necessity for a Christian basis of society if a new world order safeguarding the noblest traditions and ideals in man's inheritance, which democracy alone has preserved in the past, is to emerge out of the present chaos.

(3) Sir Alfred Zimmern's study is of an entirely different type. It makes its appeal to the scientific worker pre-eminently through its contribution to lucid thinking and its indication of the pitfalls and dangers which beset the study of international affairs. Sir Alfred, too, insists on the importance of moral and spiritual values. He appeals strongly for close study of international affairs by the ordinary citizen, but he stresses also the imperative necessity of clear and accurate thought if we are to realize a new world order which will adequately safeguard our heritage.

It would indeed be difficult to find a finer stimulus to such thinking than this compact little volume of cautionary wisdom. How many fatal mistakes might have been avoided had there been more scientific thought about international affairs in place of the disposition to regard the League as a short cut to Utopia, and to forget that it only marked the beginning of a new phase of world order, or that a League policy involved the participation and interests of many, not of one nation. What Sir Alfred says of the intellectual confusion due to the intrusion of religion into the discussion of problems on which religion by itself could offer no safe guidance has a bearing on many similar matters involved in the relation of science and society, the significance of which the scientific worker who reads this book can scarcely fail to appreciate.

There are indeed sections in this book in which Sir Alfred seems to be expanding the scientific method itself, and his chapters on the War of

1914–18 and its aftermath, on peace, on our English burden and on the Colonial problem could scarcely be bettered as an aid to lucid thinking about the problems of world order which will confront us after the present war. Apart from this, Sir Alfred insists that there are three necessary stages in the process leading from the prevailing anarchy to some form of world organization. Peace—the cessation of actual fighting—is only the first of these. The second is order, or what is sometimes called the stage of the hue and cry—the stage at which violence is prevented or punished by the public spirit of the citizen body, the leading democratic peoples. The third stage is that of law, where the habit of co-operation developed through common action in repressing violence has hardened into social rules for the conduct of what has then become a common social life.

The phrase "law and order" has probably been responsible, as Sir Alfred points out, for much false thinking in this sphere, and to convert it into real "order and law" should conduce to the lucidity essential in our thinking about a new world order. The scientific worker will, however, find neither here nor elsewhere in these three volumes the 'blue prints' of the world order which he in common with other lovers of truth and freedom desires. He will, however, find much that is stimulating, much that is corrective of confusion and much that should encourage him to take his own part in the travail out of which the order will be born. Nor should he be ungrateful for the evidence the volumes afford of the widely diverse fields in which men are turning their thoughts to such constructive purposes, and of the grounds for confidence in the power of democracy to prevail over the forces now threatening all that is noblest in man's moral, spiritual and intellectual heritage.

R. BRIGHTMAN.

HYDROCARBONS

Physical Constants of Hydrocarbons
Vol. 1: Paraffins, Olefins, Acetylenes, and other Aliphatic Hydrocarbons. By Gustav Egloff. (American Chemical Society Monograph Series, No. 78.) Pp. 412. (New York: Reinhold Publishing Corporation; London: Chapman and Hall, Ltd., 1939.) 45*s*. net.

IT has become almost a commonplace to refer to the tremendous advances which have taken place in the field of hydrocarbon research. A very large and prosperous industry has come into being almost entirely as the result of scientific research, and its leaders have realized that money must be devoted on the grand scale to such research if it is to continue to expand.

The relatively simple hydrocarbon with only two elements—carbon and hydrogen—and a straight-chain formula was almost despised not so many years ago by chemists busy unravelling the complex structures of the anthocyanins and the alkaloids, the purins and the proteins. To-day they are in the forefront of interest in many laboratories, largely as the result of the stimulus given to the exploration of the vast number of different hydrocarbons present in crude petroleum by industry's demand for new products.

For industrial purposes, fractions of the original crude of wide range of boiling point at first sufficed. Modern practice demands fractions of much smaller range, and the individual hydrocarbons are beginning to have possible technical significance. An exhaustive separation of the individual hydrocarbons is being effected as the result of co-operative research at the Bureau of Standards in Washington, and compounds which have hitherto received no attention are the object of experimentation.

The modern high-compression engine demands a special fuel with a high octane number, as the oil men term it. Straight-run or even cracked spirit alone does not suffice, and there is an indication that the fuel of the future will be a petrol re-formed from the hydrocarbons after cracking and catalysed synthesis. More and more the hydrocarbons are coming to be regarded as the primary raw materials for industrial organic syntheses.

The hydrocarbons are largely identified by four physical constants: melting point, boiling point, specific gravity and index of refraction. For a long time there has been an urgent need for a critical digest of all data pertaining to these. Such a systematic study has been going on in the laboratories of the Universal Oil Products Company in Chicago, and it is to be published in four volumes, of which the first is now before us. The first three volumes will contain the physical constants, whilst volume 4 will deal with their inter-relationships as well as correlating physical properties with structure.

The first part covers the open straight- or branched-chain hydrocarbons, namely paraffins, olefins, acetylenes and other aliphatics: they are actually grouped into ten sections. The procedure adopted is described in a short introduction and the rest of the book consists entirely of tables. Everything is very clearly printed and most easy of reference.

Dr. Egloff has long been a pioneer in research in the oil industry ; indeed I think he was one of the very first to envisage the future importance of hydrocarbons as opposed to mere oil. His knowledge of the subject is profound, and though it has been always freely made available to those who sought it privately, the fact that he has now consented to turn author is of inestimable service to every industry in which hydrocarbon chemistry plays a part. His previous work on the "Reactions of Pure Hydrocarbons" has already become indispensable to us as individuals ; his physical constants will be consulted as often in oil laboratories as is the "Oxford Dictionary" by writers.

Such a book must necessarily be costly, though the price is of no importance in industrial laboratories in relation to the utility of the book, which is of the type which does not grow out of date and will remain a standard reference book for many years to come. It is a monument to the name of Egloff.

E. F. Armstrong.

ORDNANCE AND GUNNERY

Elements of Ordnance

A Textbook for Use of Cadets of the United States Military Academy. Prepared under the direction of Lieut.-Colonel Thomas J. Hayes. (A revision of the "Textbook of Ordnance and Gunnery", by Colonel Earl McFarland.) Pp. x + 715. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1938.) 32*s*. 6*d*. net.

THIS is by no means a new book. In its present form it appeared in 1938. But like most service text-books it is a compilation which represents a more modern version of an earlier work. It is none the worse for that. On the contrary, it is well written, well and lavishly illustrated, and it is excellently produced. The index, as befits a work of reference of this extent, is full and satisfactory.

The ground covered is very wide indeed and may be briefly indicated. Three chapters on propellants, explosives and metals deal with the relative parts of physical chemistry and metallurgy. Six chapters of a more or less theoretical kind deal with internal and external ballistics, including probability, gun construction and recoil, and bombing from aeroplanes. This last indicates that the range of subjects treated is even wider than the limits which apply to the gunner. The remaining chapters, ten in number, are essentially descriptive. They cover the design of breech mechanisms, types of artillery, sights and fire control instruments, including the equipment used in conjunction with anti-aircraft artillery, gun ammunition and fuses, small arms and the corresponding ammunition, bombs and grenades ; a short chapter on the properties of light armour leads to one on mechanical vehicles. These are, in the main, tanks. Carriages are described in connexion with the corresponding types of artillery, coast defence or mobile, but the subject of tractors seems to have been dismissed more summarily. Tables at the end of the book provide useful data from physical chemistry.

The mere recital of the contents of this book should serve to show how vast is the field which lies before the modern artillerist. For all its seven hundred pages this is only an introduction to the subject, and a very good one. It is intended as a text-book for the First Class in the West Point Military Academy. As such it is supplemented by lectures and shop and laboratory practice. At once it is suggested that the U.S. cadet who is destined to find his career as a gunner leaves the Military Academy with a preparation far in advance of his opposite number in Great Britain. Whether it has been sufficiently realized that modern developments have made the subject of artillery a highly scientific branch of activity, demanding the service of the most gifted and the most highly trained brains, is a question which deserves the most serious consideration. It is not, of course, to be assumed that every young American gunner absorbs all the fare that is set before him.

For the general reader and even for some whose concern with the subject is more specialized, the most interesting and valuable chapters are probably the descriptive. Naturally, American equipment, methods of manufacture and designs are treated exclusively. But under the stress of modern rivalry the types of armament employed in different countries tend in the main to close similarity. It is in points of detail that the chief differences will be found. Against a single national point of view, moreover, a compensating advantage is to be set. There is no trace here of that atmosphere of secrecy, generally futile, on which most military authorities insist. It would, of course, be unsafe to infer that the whole of American practice is revealed without any reservation whatever. But there is a refreshing absence of that concealment which serves no useful purpose and only tends to make legitimate instruction difficult.

The chapters which deal with the mathematical theory are less satisfactory for the simple reason that they are of necessity too short to furnish more than an introduction to this aspect of the subject. They have no other noticeable fault and within their prescribed limits they are highly instructive. Thus while the account of external ballistics is so brief that the serious student will need to supplement it by consulting some at least of the standard books and original memoirs, of which a good list is appended to the chapter, the subject of yaw is treated in some detail. The effect of probability on the fall of rounds is discussed in a separate chapter. It seems curious that nowhere is the normal law of frequency more implicitly accepted than by gunners, who at the same time are very ready to reject rounds which appear to be anomalous. The inclusion of the subject of bombing from the air serves to remind the reader of the mutual relations which obtain in different countries between the army and the air force, and of the fact that the complete separation of the two forms of national defence is apt to entail some loss of a common understanding of technical problems.

Of internal ballistics it is said that "Interior ballistics is not an exact science". It is a complex problem certainly, yet the elements for its solution lie in physical chemistry and in mechanical conditions which should be capable of definition. An exact answer may not always be beyond the range of possibility. But there are two obstacles in the way. In the case of a problem which is at the same time highly complicated and of practical importance, the temptation is strong to avoid the scientific investigation of all the underlying factors and to reach the end in view, which is to predict the performance of a newly designed gun, in more summary fashion. Here, since all arsenals possess the records obtained by firing guns of many types, the empirical method of interpolation, or extrapolation, is commonly employed. But this does not mean that a more scientific treatment, in which considerable progress has already been made, can never be brought to practical perfection.

The chapter on recoil is one of the best in the book, but that on gun construction is far less satisfactory. The method of wire-winding is naturally dismissed shortly, for it has been superseded, though effective guns of this type remain in the U.S. service. The built-up gun may also be doomed to disappear. It is disappointing that the theory of auto-frettage has not been discussed at greater length, though this process of manufacture is fairly described. Both the 3-in. and the 105-mm. A.A. guns of the American service consist of an auto-fretted tube with loose-liner. But it is interesting to learn that the same service has adopted a 155-mm. howitzer which is an auto-fretted tube without liner; it is stated that this monobloc construction greatly reduces the cost and is easily replaced in the field. What steel is used in this weapon is not mentioned, and though the properties of various modern alloy steels are described no figures seem to have been given for the high elastic limits which can now be reached with increasing ease and certainty. It does not seem impossible that the process of auto-frettage with its obscure theory will go the way of other methods now abandoned, and that the gun of the future will be a simple monobloc, with or without a loose liner.

H. C. PLUMMER.

USELESS MATHEMATICS

Mathematical Recreations and Essays
By W. W. Rouse Ball. Eleventh edition, revised by H. S. M. Coxeter. Pp. xvi+418. (London: Macmillan and Co., Ltd., 1939.) 10*s*. 6*d*. net.

EVERY former reader of Rouse Ball's classic will rejoice that a new edition has been brought out. They will miss some old acquaintances, particularly the chapter on string figures, but they will find a good deal of new material, notably a chapter by Dr. Coxeter on polyhedra, and one by Mr. Sinkov on cryptography.

The book is remarkable in several respects. In the first place, although it demands no mathematical knowledge beyond elementary algebra and geometry, it brings its reader to the edge of mathematical knowledge at many points. Some of the unsolved problems treated are fundamental, such as the four-colour problem, that scandal of topology. Others, such as Kirkman's problem of the schoolgirls, will probably yield to combinatorial analysis without any revolutionary discoveries.

In the second place, almost all the mathematics is inapplicable to practice. The Admiralty staff are not likely to be presented with the problem of the three jealous husbands and the ferry-boat (p. 116) when arranging convoys, nor will the theory of mazes help the German General Staff to penetrate the Maginot Line. But parts of the chapter on polyhedra have an application to crystallography, and the theory of Latin squares has been extensively developed in connexion with agricultural tests. The most recent work on it is indeed published, paradoxically enough, in the *Annals of Eugenics.*

"Mathematical Recreations" constitutes an addendum to every mathematical library. I can imagine no better book for a schoolboy or girl who is taking mathematics seriously. The reader will find himself introduced to advanced topics such as topology, group theory, and prime number distribution theory, without any intellectual strain, and will learn a surprising amount of mathematics without knowing it. The more advanced reader will find some novelties in every chapter. Above all, one need not read the book systematically. On the contrary, it is an excellent bedside book into which one can dip at random.

The War may discourage mathematical reading. It need not. I remember that among a row of wounded officers on the deck of a barge in Mesopotamia in 1917, the occupant of the next stretcher to my own was reading Lamb's "Infinitesimal Calculus", whilst I was reading Kelland and Tait's "Introduction to Quaternions". But systematic study is certainly difficult, and perhaps "Mathematical Recreations" would have been more suitable.

I hope to see many more editions. I may be accused of attempting to gild the lily, but here are two suggestions for the next. Since the theory of Mersenne's and Fermat's numbers is part of the theory of recurring 'decimals' in the scale of 2, I should like to see an excursus on recurring decimals in the scale of 10, pointing out, for example, why every recurring decimal with a period of 10 must have 9091 or a multiple in its denominator; and since such formulæ as $\frac{1}{4}\pi = 4 \tan^{-1} 1/5 - \tan^{-1} \iota/239$ are equivalent to factorizations of $n + n\iota$, readers might be introduced to complex arithmetics on p. 348.

However, Dr. Coxeter knows his job better than I do, and has shown himself a worthy successor of Dr. Rouse Ball. This is the eleventh edition. May there never be a last edition.

J. B. S. Haldane.

GENERAL ASTRONOMY

(1) Astronomy

By William T. Skilling and Robert S. Richardson. Pp. xi+579. (London: Chapman and Hall, Ltd., 1939). 15*s*. net.

(2) Exploration du ciel

Par Pierre Rousseau. (Le roman de la science.) Pp. 256. (Paris: Hachette et Cie., 1939.) 20 francs.

(1) THE progress of astronomy, as regards both the methods and results of research, is in these days so rapid that there is always room for a new and up-to-date text-book on the subject. Messrs. Skilling and Richardson's book is the most recent of several that have appeared in the past few years; and it covers the whole field of descriptive astronomy in a simple style, suitable for the general reader.

The insertion of examination questions at the end of each chapter suggests that the work was intended to afford a complete elementary course for students. Unfortunately its usefulness for this purpose is much impaired by a certain lack of the balance which should characterize a really satisfactory text-book. Thus, while the subject of solar physics is treated in considerable detail (one of the authors being a specialist in this line of research), the planetary system is dealt with in a rather perfunctory way. The minor planets, for example, are dismissed in little more than a single page, while no mention is made of the variable rotation periods of Jupiter and Saturn, or of the transparency of the latter's ring system. On the other hand, the book certainly contains much up-to-date matter of great interest and value to the student. It is well supplied with illustrations, though some of the diagrams are open to criticism. The text appears, apart from a few minor errors and misprints, to be substantially accurate, but the so-called "glossary" at the end of the book is so abbreviated as to be practically useless.

A glance through the names of astronomers quoted in the index will reveal a certain parochialism which is rather common in American scientific books. But it is perhaps a pardonable weakness, and one from which no nation seems to be altogether immune.

(2) M. Rousseau's book consists of a series of popular essays on various aspects of modern astronomy. The author's avowed aim has been to humanize the subject and to emphasize the romantic side of research. To this end he devotes considerable space to the description of the more important astronomical instruments, and of the way in which they are actually used for various purposes. This seems to us a particularly attractive way of dealing with the subject, and M. Rousseau's obvious enthusiasm can scarcely fail to communicate itself to his readers, whether they be possessed of previous astronomical knowledge or not. The book seems worthy of something rather better than its present flimsy cover, and it is a pity that the quality of the paper has ruled out the use of half-tone illustrations.

W. H. Steavenson.

PHYSICS IN THE GLASS INDUSTRY

BY PROF. W. E. S. TURNER, F.R.S.
UNIVERSITY OF SHEFFIELD

IT is in keeping with the transparent nature of the substance that the first physical properties of glass to receive conscious study in comparatively modern times should be the optical properties. The problem of dispersion in the simple telescope lens found a partial solution in the achromatic lens combination of John Dollond in 1758, and the subsequent development of lens systems, in which the correction of chromatic aberration is still more complete, has involved the utilization of glasses of different and precisely known refractive indexes and dispersions. The work of Guinand, of Faraday, of Harcourt and of Schott was in all cases concerned with the production of better glasses of constant optical properties, or of new glasses permitting a wider range of optical properties for use in combinations.

With the work of Schott, however, there was opened up the possibility of exploiting some of the new glasses experimented with, for purposes other than components of optical instruments. Thermometer glasses of low after-contraction were one development. The accumulation of general physical data about glass had set in at Jena, so that, between about 1883 and 1895, many data were compiled about density, thermal expansion, thermal conductivity, tensile, compression and other aspects of mechanical strength ; and although in recent times some of these data have had to be drastically revised, they led to the manufacture of a variety of new glasses for heat resistant and other purposes, and pointed to the usefulness of certain compound glasses.

For the next twenty years, the impact of physics on the industry was less exciting and dramatic, but some of the results at least contained the seeds of later important developments. Then began an altogether new period in which striking individual results of physical studies led to new types such as Pyrex and other low thermal expansion glasses ; R. W. Wood's glass ; the Corex glasses, etc., side by side with the development of revolutionary processes in which highly productive automatic machinery began rapidly to displace the hand worker. The manufacture of glass bottles and containers in thousands of types ; of sheet and plate glass ; of electric light bulbs ; of glass tubing and rod and of some types of domestic glassware has within the past twenty to twenty-five years been transferred almost entirely to highly productive automatic machines, the efficient functioning of which was, in a number of cases, achieved only after many years of development.

It is in these fields of manufacture that the bulk of the capital of the industry is locked up. That represented by optical and scientific glassware of all types is relatively insignificant. The development of several of these automatic machines was in the early years in the hands of the clever mechanic, with no background of systematic knowledge of physics and chemistry, or even of the fundamental principles of engineering. It has been the service of the physicist to work out processes of control so as to maintain constant conditions under which the machine can operate favourably. As an illustration, it may be mentioned that with one automatic machine, the temperature of the molten glass (at 1140–1160° C., according to size of article to be made) in the bath from which the machine takes its own supply many times per minute, must be kept constant to ± 5° C. ; and high-temperature pyrometry, glass-level control in furnaces holding huge quantities of the molten material, and various other problems have had to be worked out suitable for each set of conditions of operation. At every stage of mass manufacture, speed and efficiency involve fundamental knowledge, and it is not surprising, therefore, that the widespread employment of physicists and chemists has really only begun with the introduction of mass manufacture.

Some conception of the part which the physicist plays both in the development of new types of glass and in the manufacturing control of others was clearly brought out during a discussion on February 15 on the subject of "Physics in the Glass Industry", held at the Royal Institution under the auspices of the London Branch of the Institute of Physics. The contributors of papers to the symposium were Dr. Harry Moore on "Strains intentionally introduced during Glass Manufacture", Dr. W. M. Hampton on "The Spectacle and Optical Glass Industry", Dr. Eric Seddon on "Physics in the Manufacture of Glass Bottles", Dr. B. P. Dudding on "Glass for Lamps and Electronic Devices", and Dr. J. H. Partridge on "Refractories used in the Glass Industry".

In the manufacture of spectacle and optical glasses, physical methods continue in the line of traditions of fifty or sixty years ago, though with some important developments. Both types of glasses must be controlled in respect of refractive index so that repeat meltings are kept within ± 0·001 of the desired value for well-annealed samples. The Pulfrich refractometer is normally employed for this control and has an accuracy of one in the fourth place of decimals on refractive index and two in the fifth on dispersion; but master standard prisms of optical glasses of refractive indexes and dispersions measured to a few units in the sixth place of decimals are used to control the Pulfrich observations. Modern optical glasses must also have a light absorption of not more than a fraction of 1 per cent per inch thickness, and the amount which occurs in the visible, ultraviolet and the infra-red has been the subject of close study and control, the main cause of absorption being the presence of very small amounts of iron oxide in solution. Spectacle glasses, on the other hand, may have colour dependent on the purpose for which they are intended, such as protective goggles for use by welders, and in all such cases the transmission in the three spectral regions must be determined as a routine control measurement.

The annealing of glass has received much detailed scientific and practical study during the past twenty years, in particular by Twyman and by Hampton in England, and by Adams and Williamson in the United States, in regard to general theory, and by English and Turner in regard to the relation of composition to the annealing temperature. The latter quantity is usually related to the viscosity, on which property of glass much work has been done in recent years. At the highest temperatures used in melting a glass, the viscosity is usually reduced to not more than 100 poises, but with fall of temperature the increase of viscosity is such that at room temperature it should be of the order of 10^{20}. The viscosity corresponding to annealing temperature conditions lies between 10^{12} and 10^{13} poises, rapid removal of strains, that is, rapid annealing, being possible at the lower viscosity figure or higher temperature, slow annealing resulting at the higher viscosity.

The annealing temperature chosen depends on the character of the glass, on its size and thickness and the degree of strain permissible. In mass-produced glass the object is to anneal as speedily as possible, and the higher annealing temperature is accordingly chosen. In modern glass bottle annealing, as illustrated by Dr. Seddon, the glassware is annealed and cooled nearly to room temperature in less than two hours. In the case of the Fourcault sheet glass process, producing an article of simple shape and uniform thickness, it is a matter of only a few minutes before the flat sheet, drawn out of a bath of molten glass at approximately 1000°, emerges from the annealing shaft at a temperature cool enough to enable it to be carried safely in the open air. On the other hand, in the case of large slabs of optical glass, it is not unusual, as Dr. Hampton pointed out, for the annealing process to involve heating them slowly from room temperature up to the annealing temperature in five to six days, to maintain them for 24–70 hours at that temperature and then to cool them during the first 150° below the annealing temperature at a rate of perhaps only 10° per day. In the case of a large telescope disk, such as the famous 200 in. disk, the cooling must be spread over several or many months.

Control of the distribution of strains in the flat-drawn sheet glass prepared either according to the original Fourcault process or its modification the Pittsburgh process, is important if excessive breakage is to be avoided. In either method, there is some contrivance whereby the edges of the sheet, which may be more than 100 in. wide and up to ¼ in. thick, are chilled and maintained rigid so soon as it is raised above the molten glass. This results in these edges being put into compression vertically as the temperature becomes uniform, whilst the centre develops tensile strain vertically, there being other tensions and compressions across and through the sheet. The tensile strains must not reach the breaking limit and must be so distributed as to leave the sheet substantially free from strain when, as is part of the normal operation, the edges are cut off. Dr. Moore described an elegant method now under trial of using Babinet compensators to maintain routine observations on the edges and centre of the sheet as it emerges from the drawing tower.

The physicist has also been set a problem by no means easy in the testing and control of 'toughened' glass produced by heating plate or sheet glass to a temperature some 50° C. above the annealing point and chilling it rapidly by a blast of cold air from many small orifices, the result being to multiply several-fold the forces which it will withstand before fracture. The compressive forces thus introduced into the surfaces are such that the glass sheet can be bent or otherwise deformed considerably before these compression strains are removed and replaced by tensile strains under which glass almost invariably breaks, since the tensile strength is only one eighth to one tenth of that of the compression strength. Here control may be exercised by a combination of mechanical testing methods and of the tensile strains measured optically either on pieces cut from lightly 'toughened' plate or on 'toughened' thick plates of glass convenient for edgewise examination.

The Babinet compensator has also been a valuable tool in the study and control of permissible stresses in vacuum-tight glass-to-metal seals in electric lamps and valves; and of flashed opal glasses, Dr. Dudding having some excellent coloured slides to show of strain patterns; whilst Dr. Hampton illustrated its use in the manufacture of bifocal lenses. In such a lens the major part consists of spectacle crown glass, into a depression of which a button of glass of higher refractive index is fused, and the whole then ground down to the required curvature. Satisfactory welding is found to require, for similarity of thermal expansion, coefficients of the two glasses to within $\pm 2 \times 10^{-7}$. Since 1920, many investigations of this property have shown that the thermal expansion–temperature curve deviates considerably from a straight line and at a transformation temperature the coefficient increases several-fold. The successful solution of the problem of obtaining two glasses, or a metallic wire and a glass, of thermal expansion curves closely agreeing with one another, is a testimony to the thoroughgoing nature of the study of this subject.

Researches on the electrical properties of glasses have had various practical applications, nowhere perhaps more vitally than in the electric lamp industry. By systematic researches on the relation of composition to electrical resistance, glasses have been made available for mercury vapour discharge lamps which will permit of their operation at temperatures of 600° and yet have a resistance 300,000 times that of the simple soda-lime-silica glasses used in 1916*, and offering prolonged resistance to blackening.

Not merely in the operations of glass fabrication and manipulation but also in auxiliary processes in its melting, modern physical methods have received valuable application. In the study of the performance of refractory articles in which glasses are melted, X-ray methods of examining structure have often led to vital knowledge; and tensile strength and creep tests at high temperatures, as Dr. Partridge showed, have been of great value.

Some fields of investigation have been but little explored by the physicist. Thus, Dr. Seddon emphasized the lack of systematic information available about certain thermal properties at high temperatures, namely, specific heat, thermal conductivity and emissivity. But sufficient has been said to demonstrate how physics has assisted in transforming glass-making into an enterprising and efficient industry.

THE FLORA OF MADAGASCAR

By Dr. J. Hutchinson,
Royal Botanic Gardens, Kew

FEW naturalists will need reminding that Madagascar, the third largest island in the world, possesses a fauna and flora of exceptional interest. Although only 260 miles distant from the nearest point on the East African coast, its flora bears an almost equal relationship with that of the great continent and that of Ceylon, Malaya and even Australia, whilst its fauna, as pointed out long ago by Alfred Russel Wallace[1], is almost exclusively related to that of Eastern Asia. Of equal interest is the fact that the language of the natives is closely related to those of Malay-Polynesia, whilst another remarkable feature is that they do not employ skins for clothing their bodies as do the natives in Africa, but make use of vegetable fibres as do the eastern peoples.

The distribution and affinities of the animal life, therefore, and of the plants in part, indicate that Madagascar was in former times connected much more closely with the continent of Asia than it is at the present day. As is well known, there are two rival hypotheses which might account for these interesting facts, either the mythical Gondwanaland of Suess, or the continental drift of Alfred Wegener. With respect to its organic life, therefore, Madagascar ranks equally with other oceanic islands such as New Guinea, New Caledonia, St. Helena and the Galapagos in being a 'museum of antiquity'.

Madagascar is nearly a thousand miles long, has an average of 250 miles in breadth and an extreme width of 360 miles. Its area is nearly four times that of England and Wales.

The main features of the island are the great central ridge of elevated ground, the encircling tropical plains, broad on the west side, narrow on the east of the ridge, and with a long girdle of primeval forest nearly 2,000 miles in length. There is fine mountain scenery in the Betsileo country in the southern portion of the island, and in the centre the Ankaratra mountains rise to a height of 9,000 ft. within a short distance of the capital, which stands at 4,000 ft. This central portion consists of rolling moor-like hills covered principally with long grass which becomes very brown and dry by the end of summer.

The flowering season of most plants in Madagascar is October–May, that is, during the rainy season. But many do not flower until December, and the grasses and sedges mostly flower towards the colder dry season, from March to May.

The plant that probably leaves the greatest impression on the visitor is the travellers' tree, *Ravenala madagascariensis* Sonn., a banana-like plant, but more closely related to the well-known South African Strelitzia than to the banana (Musa). A beautiful flowering tree is Colvillea, a leguminous plant of the family Cæsalpiniaceæ, with sensitive leaflets like those of a Mimosa, and a dense raceme a foot long of large red flowers with rounded petals.

One of the best known Madagascar herbs is Kitchingia (Crassulaceæ) (united by some botanists with Bryophyllum), which is grown in hanging baskets in our greenhouses. It commemorates the late Langley Kitching of Leeds, a missionary who collected plants in Madagascar in 1879.

Until nearly the close of the nineteenth century we knew very little of the botany of the island. The great world-exploring expeditions up to that time and to which botanical collectors were attached had mostly given it a wide berth and proceeded direct from the Cape to Indo-Malaya and Australasia, and the opening of the Suez Canal tended to increase this neglect. It was not until 1820, when Christian teaching was commenced by the London Missionary Society, that Europeans gained access to some parts of the island. A set-back soon occurred, however, for on the death of the native King Radama in 1835, missionaries were obliged to leave the country by command of Queen Rànavàlona, the native Christians were persecuted, and for many years all Europeans were excluded and foreign commerce brought almost to a standstill. In 1861, however, the island was reopened to European trade and missionary efforts recommenced, the independence of the country being more or less maintained until 1895, when it became a part of the empire of France.

Botanical exploration did not begin in earnest until about 1880, when large collections began to arrive at Kew from members of the London Missionary Society, mostly made by Mr. Langley Kitching, Dr. Parker and the Rev. R. Baron. The last-mentioned, for example, sent to Kew between the years 1880 and 1896 nearly 12,000 specimens (separate gatherings) of plants. These were dealt with by the late Dr. J. G. Baker, then principal assistant in the Kew Herbarium, and the novelties were described by him in the *Journal of Botany* and the *Journal of the Linnean Society*. To these two men, therefore, should be given the credit for laying the foundations of our knowledge of the flora. Baron's plants were particularly valuable because they were collected in the central higher parts of the island, especially the Imerina Province, and many of them proved to belong to genera and species hitherto unknown to science.

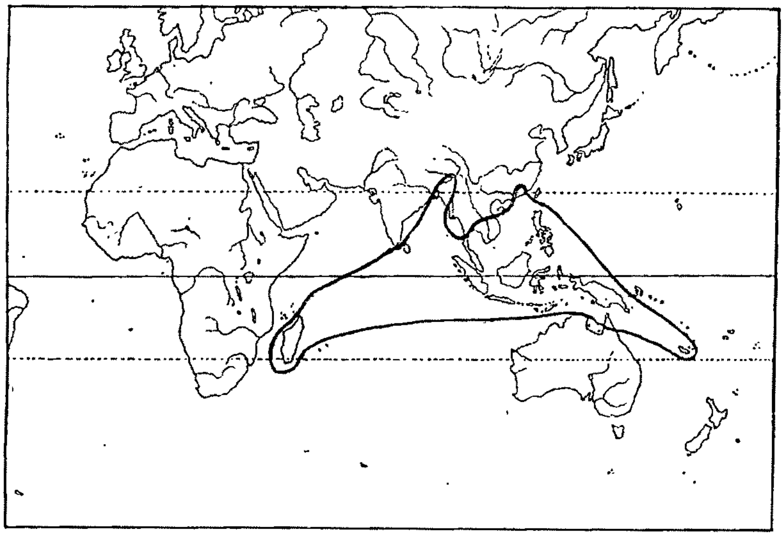
The principal British collector since Baron's time was Mr. G. F. Scott Elliot, who explored the southern part of the island in the neighbourhood of Fort Dauphin, and collected more than a thousand plants.

In more recent years large collections have been made by H. Perrier de la Bathie and by the present director of the Paris Botanical Museum, Prof. H. Humbert, and the mantle borne by Baron and Baker has very appropriately passed to the shoulders of these two French botanists. They also have brought to light many new species and new facts relating to the distribution of Madagascar plants.

In 1936 a "Flore de Madagascar" (Plantes vasculaires) was commenced under the direction of Prof. Humbert, and it would indeed be a tragedy if this important work were to be delayed because of the War. In common with other countries, after it is over, France will no doubt need as much detailed knowledge of the vegetable productions of her possessions as possible, and nothing contributes so much towards this end as a well-written and illustrated Flora such as contemplated by the Paris botanists, a portion of which has been published already[2], and further parts are in preparation.

For example, Madagascar possesses one of the most remarkable grass floras in the world, including a number of endemic genera of bamboos. Very few of them have so far been investigated for economic purposes. The soil of the plains is described as rich and very fertile and capable of supporting vast herds of cattle, and it should not be forgotten in this respect that the island is about as big as France herself. It is indeed high time that botanists should know more of the flora in a collected form, for up to the present we have only had available miscellaneous papers published in many different journals, from which it has been well-nigh impossible to obtain an adequate idea of the flora as a whole. Then, and then only, will it be possible to study the many interesting phytogeographical problems which the island presents in abundance.

I may mention only a few of the more prominent. For example, why is it that there are in Madagascar no species of Mesembryanthemum (*sensu lato*), so numerous in South Africa, when there are in the island numbers of spiny Euphorbias, Pachypodium and xerophytic Asclepiadaceæ, which are such prominent features of the South African vegetation? In addition, such typical South African genera as Halleria (a woody Scrophulariaceous



RANGE OF THE UNIQUE GENUS OF 'PITCHER PLANTS' (NEPENTHES) (AFTER HUTCHINSON: "FAMILIES OF FLOWERING PLANTS", VOL. 1).

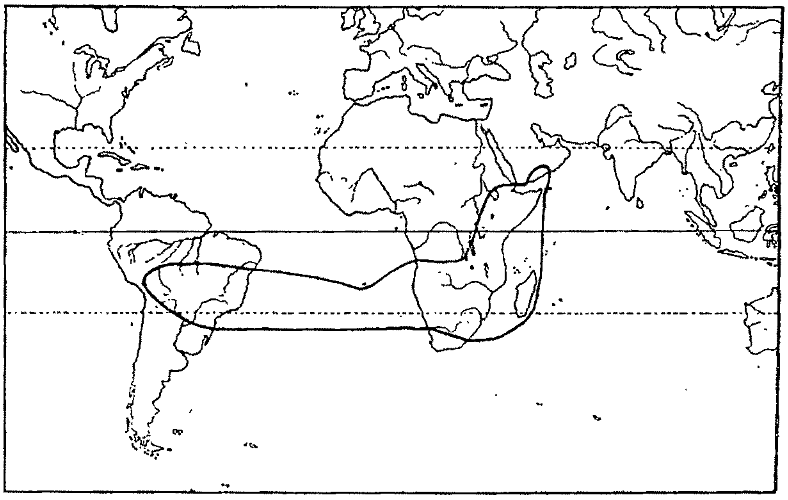
genus), Clematopsis (Ranunculaceæ), Sparrmania (Tiliaceæ), Faurea (Proteaceæ), Peddiea and Däis (Thymelaeaceæ), Kniphofia ('poker plants'), Aloe (Liliaceæ), and Aristea (Iridaceæ), are also prominent in the vegetation of Madagascar.

Again, is Madagascar the original home of the Baobab genus, Adansonia ? There are more species in the island than elsewhere, for there is only one in the whole of tropical Africa, and two in northern Australia. This connexion with Australia is mysterious and is reflected again in the case of Hibbertia (Dilleniaceæ), a large Australian genus with two endemic species in Madagascar. And how did the unique genus Nepenthes (pitcher plants) get to Madagascar, all the other species being in Ceylon and through Malaya as far as New Caledonia (see accompanying map) ? Ocean currents did not carry them ; nor did the flight of birds ; nor were the seeds borne on the wings of the wind !

Madagascar has at least two endemic families of plants. These are Chlaenaceæ, related to the great Asiatic tea family, Theaceæ, and Didieriaceæ, the latter being weird spiny plants of fantastic form and uncertain affinity, which have almost to be seen to be believed. At present we know far too little about them until they are more thoroughly investigated in the field and collected.

As stated above, the flora is only in part related to that of tropical Africa. The most striking genera common to the two regions are Brexia (Escalloniaceæ), Dombeya (Sterculiaceæ), Acridocarpus (Malpighiaceæ), Haronga (Hypericaceæ), Uapaca (Euphorbiaceæ), Myrothamnus (Myrothamnaceæ), Agauria (Ericaceæ), Psiadia (Compositæ), Landolphia (Apocynaceæ), Albizzia Sassa (Gmel.) Macbride (Mimosaceæ), and Trachylobium (Cæsalpiniaceæ), the East African copal tree, all genera or species familiar to African but unknown to Indian botanists. Most of these trees and shrubs grow in the great primeval forest which encircles the whole island at a distance of about forty miles from the coast, but which extends right to the sea at the north-west end of the island. According to Humbert, this forest is fast disappearing on account of the shifting native cultivation just as in tropical Africa, and it is of primary importance to biological science that it should be thoroughly explored and comprehensive collections made before it has been destroyed.

An interesting Madagascar-Afro-American connexion is shown by the genus Vellozia (Velloziaceæ), a distinctive monocotyledon, with shrubby stems and star-like flowers, of which there are several species in Madagascar, tropical Africa and South America, with one in southern Arabia. More surprising in this respect is the recent discovery of a new species of grass belonging to the genus Redfieldia, hitherto monotypic and known



RANGE OF THE GENUS VELLOZIA (AFTER HUTCHINSON: "FAMILIES OF FLOWERING PLANTS", VOL. 2).

only from the United States of North America. Although accepted by agrostologists, this is more likely to be due to convergent evolution such as is common in Compositæ and other large homogeneous families as Cruciferæ, Papilionaceæ, Rubiaceæ, Asclepiadaceæ, and Labiatæ. The grasses also provide a further example of the Indo-Malayan connexions of the flora, for a species of the genus Thuaria (*T. Perrieri A. Camus*), until recently known as monotypic in Indo-Malaya and Polynesia, has now been found in Madagascar.

FOOD RESEARCH

BY DR. T. F. DIXON

THE Department of Scientific and Industrial Research has recently issued the annual report for 1938 of the Food Investigation Board under the chairmanship of Sir Joseph Barcroft*. The report describes experimental work carried out under the general direction of Mr. Eric Barnard, at the Low Temperature Research Station, Cambridge, with sub-stations at Covent Garden and Smithfield, the Torry Research Station, Aberdeen, and the Ditton Laboratory, Maidstone.

The most important development during the year under review has been the expansion of the work of the Board to cover research on the processing of food. A committee has been set up to consider the organization of research in this field in the interests alike of the consumer, producer and manufacturer. As soon as research on processing is considered, the question arises as to whether it should be organized on the basis of the process, for example, canning, or of the raw material, for example, fruit and vegetables or meats. The Board takes the view that it is the research on the raw material that is fundamental.

Although some work has been already carried out on the manufacture of bacon, the smoking and salting of fish and the canning of fruit, the work of the Board had previously been mainly concentrated on the problems involved in preserving the 'fresh' properties of unprocessed food during transport and storage.

Attention is directed to the progress made in the transport of chilled beef from Australia and New Zealand by gas storage, that is, in stores on board ship the air of which is enriched to a controlled extent with carbon dioxide. Until this method of storage was developed meat could not be brought from these distant Dominions to Great Britain in a chilled condition; it had to be frozen. In the five-year period since the method was introduced, the exports to Great Britain from Australia and New Zealand of chilled beef have increased nearly ten-fold to a combined annual figure of 42,500 tons. Since chilled beef has recently commanded a premium of 1*d.* a pound over frozen beef, the increased value of this meat is of the order of £400,000. The possibility of improving the 'bloom' or appearance of the meat, which depends on the condition of the layer extending inwards to a depth of about 1/10 inch, by increasing the evaporation of water from the meat during the voyage, is also being investigated. Acidification of flesh occurring after death takes place in two stages. The first, ending at *p*H 6·2, is dependent on the physiological state of the muscle and is uninfluenced by temperature. The second stage, however, is influenced by temperature and probably represents a straightforward enzymic breakdown of glycogen. Stiffening (rigor mortis) also takes place mainly during the second stage of acidification. The higher the glycogen content at death the lower will be the muscle *p*H and the firmer the flesh. Liver and muscle glycogen levels are usually much lower in pigs than in oxen.

The average value for the ultimate *p*H (twenty-four hours or more after death) of the pig psoas muscle has been used as a measure of the muscular fatigue of the animal at the moment of death. A *p*H of 6·7 is taken as indicating extreme, and a *p*H of 5·5 or lower an absence of, fatigue. Empirically it has thus been possible to detect fatigue, ascribe the reason for it and devise methods to reduce it. The psoas muscle is more affected by fatigue and therefore almost always has a higher *p*H than the less deeply seated longissimus dorsi muscle. While the bacon pig is being fattened, an increase in the percentage of fat in the muscular tissue is accompanied by a corresponding decrease in the iodine value of the fat. By greatly reducing the plane of nutrition it has been possible to reduce the fat in muscle to as little as 0·5 per cent.

---

* Report of the Food Investigation Board for the year 1938. (H.M. Stationery Office.) Pp. 277.

Experiments on the quality of the eggs laid by the hens, White Leghorn and Light Sussex, show that the percentage of thick white is primarily a characteristic of the individual hen and that there is no correlation between it and the season, the rate at which the eggs are produced or their weight. Any method of washing increases the number of rots in eggs, since the organisms responsible for rotting readily penetrate the wet shell, although the permeability of shells varies widely even in successive eggs laid by the same bird.

Work on the quality of kippers carried out for the Herring Industry Board shows that the quality of the kipper varies with the content of fat. The fatter the kipper the more palatable it is. A large proportion of the kippers made from herrings cured from February to early May would be made from herrings containing less than 8 per cent of fat. The abrupt and extensive rise in the content of the fat in June from about 2 per cent to more than 20 per cent has a peculiar effect on the suitability of the herring for kippering. The newly acquired fat is apparently held very loosely, runs away readily in the kiln, and the fish is very soft and easily torn, so that great care must be observed in curing. By July, however, consolidation of the fat has taken place and the fish make excellent kippers. The great variation in the composition of the herring makes it impossible to avoid great variation in the quality of kippers even should the process of kippering be rigidly standardized.

Electrometric and chemical methods have been used for estimating freshness of fish. With haddock, for example, estimation of either di- or trimethylamine can be used to determine the onset of definite staleness; but the course of deterioration before this stage is reached can only be followed by the determination of dimethylamine using a sensitive colorimetric method. The micro-organisms causing spoilage of salted fish known as 'pink' belong to the Serratia and Micrococcus groups. The only method so far found effective for controlling 'pink' is chilling the fish to temperatures below 5° C. During the year members of the staff of the Department's Fish Research Station at Aberdeen spent a period in Norway studying at first hand the methods employed there for the handling and storage of fish and the research on the subject in progress in that country.

During the year, arrangements were made to carry out on behalf of the Government of Palestine a survey of the wastage of oranges during transport. The temperature in the holds is an important feature in the wastage of the fruit, and the main object was to ascertain how far temperature variations were responsible for the wastage and to what extent these temperatures might be improved. Experiments were also carried out on the storage conditions of Palestinian grapefruit after its arrival in England. Further successful experiments on the gas-storage of home-grown pears, apples and broccoli have been carried out. No form of storage for apples can be reckoned successful unless it conserves their flavour, and this is especially important in the case of our finest dessert variety, Cox's Orange Pippin. A full-scale demonstration was arranged to remove any doubt in the trade as to whether this variety developed its full flavour after gas storage. Twenty-six tons of Cox's Orange Pippins were put into a gas store at the Ditton Laboratory at the end of September 1937. The composition of the atmosphere of the store was 2·5 per cent oxygen, 5 per cent carbon dioxide and 92·5 per cent nitrogen and was obtained by the removal of the excess of carbon dioxide by a scrubber of commercial design together with controlled ventilation. The temperature of storage was 4° C. The store was opened on February 22, 1938, in the presence of some 150 fruit-growers and other experts. The demonstration was completely successful, the fruit being in excellent condition; in fact 80 per cent of it was graded as 'Fancy' or 'Extra Fancy'.

On the other hand, a subsequent survey of fruit of this variety from ten representative areas has shown that the extent to which the flavour is developed depends, in the main, on the pre-storage conditions, such as soil, manurial treatment and maturity at the time of gathering. Gas-storage also lengthens the life of home-grown pears of the variety Doyenne du Comice. On removal to air after five months storage, the pears ripen in twelve days at 18·3° C. and in twenty-one days at 10° C. It is found inadvisable to store late varieties of apples together with early ripe, that is, post-climacteric varieties, since volatile substances given off by the ripe apples cause a severe 'lenticel' spotting on the other fruit not only in refrigerated gas storage but also in ordinary cold storage. This 'lenticel' spotting can be produced during storage by treating the pre-climacteric apples with ethylene (1 in 500) for 2–3 weeks early in their storage life.

Confirmation of Putterill's finding in South Africa, that ripening of the plum can be stimulated by low concentrations of acetylene, has been obtained in England for the Monarch plum. After storage for three weeks at 4° C., and removal to 18° C., stimulation of ripening by acetylene, ethylene or air which had passed over ripe plums was still possible.

Other research being carried out on behalf of the Board includes work on meat, the preparation of milk fat, the storage of eggs, bacon and hams, including the factors affecting the quality of the pig's carcass, the storage of new potatoes and other vegetables, and problems connected with canning.

OBITUARIES

Sir Hubert Murray, K.C.M.G.

BY the death, on February 27, of Sir John Hubert Plunkett Murray, lieutenant-governor and chief judicial officer of Papua, the British Empire is the poorer for an outstanding figure, and there can be few of those who came into contact with "H.E." who have not felt also a sense of personal loss.

Sir Hubert was born in Sydney in 1861, and after a brilliant university career in England, was called to the Bar. He served with distinction in the South African War; but his real life-work began when he went to British New Guinea in 1904 as chief judicial officer. When this country was placed under Australian administration as the Territory of Papua in 1906, he was appointed acting administrator and shortly afterwards lieutenant-governor. He found himself responsible for a little-known country nearly twice the size of England, populated by a thin sprinkling of white settlers and an unknown quantity of Stone Age savages.

During Sir Hubert's administration a large part of Papua has been opened up. Although as time went on his administrative duties made it necessary to delegate the work of exploration to others, he kept in personal touch with as much of the Territory as he could, and it was on a tour of inspection that he died, after two days' illness, at the age of seventy-eight. But he always regarded as his main task the guidance of the country through the difficult initial stages of adjustment. From the first, he had to contend with the clash of interests between the two types of population, "for if an administrator succeeds in holding the balance even between the white settler and the native, he is open to attack from the partisans of both, and the applause of either will often be a sign that he is acting unfairly to the other". He made it clear, however, that he considered it the duty of the Papuan Government not only to foster the interests of the whites, but also "to show how the civilization of the twentieth century can be introduced among people of the Stone Age, not only without injury to them but to their lasting benefit and permanent advancement".

Taking the long view, Sir Hubert steadily opposed the alienation of any land which appeared necessary to the welfare of the natives, and the introduction of Asiatic labour, although he faced severe criticism on the grounds that he was hampering the development of the country. To meet the reasonable demands of the white settlers for labour, he introduced the indenture system, hoping that free labour might eventually be substituted. He thought that the future of the Papuans, if they were to be more than mere labourers, lay in the cultivation of land for themselves, so he instituted a system of native plantations. He also appointed village councillors, who might gradually be given more authority. At the same time, he realized the harm that can be done to a primitive people by too swift destruction of their old life. His appointment of a Government anthropologist "to help us in reconciling an intelligent, though very backward, race to the inevitable march of civilization, and in finding the easiest way for its advance", has been amply justified.

His books, "Papua or British New Guinea" (1912) and "Papua of To-day" (1925), and his annual reports—very different from the usual lifeless documents—record, though modestly, the course of Sir Hubert's long tenure of office. Some measure of his achievement may be indicated by extracts from two addresses presented to him on the completion of the thirtieth year of his administration. This from the white residents: "Your Excellency's reputation in Native Administration is world-wide and firmly established. What is not so well known outside Papua is the patient, wise and sympathetic manner in which you have worked always for the protection and support of European industries, for the advancement of Papua as a colony, and for the welfare of every member of the community." This from the natives: "When we have come to speak to you, you have not closed your ears, nor have you frowned on us, but have received us and listened to us, and taken action for us. We have seen all the good things you have done and our happiness is great because of you. Therefore we all beg of you not to leave us, but stay here as our Governor for years to come. For we know you and how you have led us into the ways of your laws, treating white people and ourselves just the same. We know that you love us well, and we are full of love for you, our Governor." B. BLACKWOOD.

Mr. A. L. Tonnoir

BY the sudden death, on January 27, of Mr. A. L. Tonnoir, the Australian Council for Scientific and Industrial Research has suffered an irreparable loss. This loss is shared by the many entomologists throughout the Commonwealth and overseas who have from time to time benefited by his unusually wide knowledge and experience.

André Leon Tonnoir was born in Brussels in 1885. After his formal education at school and at the University of Liège, he spent several years travelling in England, France, Germany, Italy and Spain. During this period he was able to give much of his time to his outstanding interest, entomology, and incidentally to acquire a sound knowledge of six languages. However, it was not until after the War of 1914–18, when he was appointed to the staff of the Brussels Natural History Museum, that he was able to devote his whole time to his former hobby. Like many naturalists, he was especially interested in Australia and New Zealand, and in 1921 he accepted a commission to study the dipterous insects of the temperate zone of the southern hemisphere, a study which still occupied his leisure hours up to the day of his death.

From Belgium Tonnoir went to New Zealand, where he worked at the Cawthron Institute, the Canterbury Museum, and the Canterbury University College, until 1929, when he joined the staff of the Division of Economic Entomology of the Australian Council for Scientific and Industrial Research in Canberra. During the past ten years he has been closely associated with research on biological control of insect pests and weeds, and has also played a prominent part in the development of an intensive study of the grasshoppers in Australia. Mr. Tonnoir's numerous papers on lesser-known families of the Diptera do not adequately reflect his remarkable knowledge of insects, although they are a record of the thoroughness of his work and his outstanding ability as a taxonomist.

Tonnoir's death removes a colourful personality and a delightful colleague, but our sadness is tempered by the knowledge that he died as he would have wished, peacefully in his sleep as he rested in the shade of a tree, after a morning's collecting in the bush. A. J. Nicholson.

Mr. H. G. Newth

Mr. H. G. Newth, whose death at the age of fifty-four occurred on February 17 after a long illness, went to school in Worcester and then entered the Royal College of Science, London. There he studied zoology under Adam Sedgwick and Mr. Clifford Dobell, and then became demonstrator in zoology for Prof. E. W. MacBride, a post which he held until the War of 1914–18. From 1920 onwards, he was lecturer in zoology in the University of Birmingham.

The early death of Mr. Newth will be deeply regretted by his friends in zoological and other circles, for he had a personal charm which endeared him to his colleagues and his students, generations of whom remember his clear lectures and skilled help in the laboratory. Advanced students profited especially from his embryological teaching, embodying practical experimental work on modern lines.

Mr. Newth was a master of microscopical technique and was always more than willing to help other research workers in the laboratory. His own original contributions included work on the embryology of Cucumaria and of Astropecten, on the development of Amphioxus, and on the swarming of Vorticella. Perhaps his most important research was on the mode of feeding of the ammocœte, which he showed to be different from that of any other animal (Nature, 126, 94; 1930). Mucus secreted by the endostyle-thyroid is moved by cilia forwards and up the peripharyngeal grooves, from which it is freed as a cone of mucous strands, uniting behind to form a mucous cord which lies free in the middle of the pharynx. This cord is continuously sucked back into the gullet by cilia in the latter. Food particles drawn into the mouth with the respiratory water current, which is maintained by muscular movements of the pharynx and of the velum, are caught in the cone of mucous strands and passed back into the gullet in the mucous cord. H. M. F.

Prof. C. Tangl

Prof. Charles Tangl, of the University of Budapest, died on January 10 in his seventy-first year. He received his early training in physics at the University of Budapest, where he was student, and later assistant and collaborator of Prof. Eötvös. He was appointed in 1901 as *Privat-Dozent* and in 1903 as professor of experimental physics at the University of Kolozsvár. In 1917 he became professor of physics at the Polytechnic in Budapest, and in 1921 he succeeded Eötvös in the chair of experimental physics at the University of Budapest. He was a member and president of Section III of the Hungarian Academy of Science.

Tangl's interests lay in three different branches of physical research. His early work was devoted to the study of the effect of magnetic fields upon the mechanical properties of solid bodies, especially of the effect upon elasticity. Then in several papers he published the results of his investigations upon the variation of the dielectric constant of liquids with pressure and temperature. These experiments, carried out with great care and accuracy, furnished very reliable values of the dielectric constants which are frequently cited. In a third line of work he applied quite new methods to investigate the forces at the contact surface of solid and liquid bodies; the determination of the contact force between platinum and water, in particular, should be mentioned.

Tangl was a man of outstanding personality and wide knowledge. A thoroughly critical judgment was combined with great kindness; he was a helpful friend to all who needed his advice. M. Forró.

We regret to announce the following deaths:

Prof. F. Emich, emeritus professor of chemistry in the Polytechnic Institute, Graz, an authority on microchemistry, on January 22, aged seventy-nine years.

Sir Thomas Heath, K.C.B., K.C.V.O., F.R.S., an authority on Greek mathematics, on March 16, aged seventy-eight years.

Prof. A. G. Högbom, emeritus professor of geology in the University of Uppsala, on January 19, aged eighty-four years.

Prof. Bernhard Lehmann, emeritus professor of chemistry and director of the Institute of Hygiene in the University of Würzburg, on January 28, aged eighty-two years.

Prof. W. C. Morgan, professor of chemistry in the University of California at Los Angeles, on February 9, aged sixty-five years.

Dr. A. J. R. O'Brien, C.M.G., chief medical adviser to the Colonial Office, on March 9, aged fifty-six years.

NEW FELLOWS OF THE ROYAL SOCIETY

AT a meeting of the Royal Society on March 14, the following new fellows were elected:

DR. W. T. ASTBURY, reader in textile physics in the University of Leeds, distinguished for his pioneer researches into the structure of natural fibres and proteins. His chemico–X-ray technique has opened up new fields of knowledge.

DR. G. R. DE BEER, reader in embryology, University College, London, distinguished for his original contributions on the embryology of vertebrates, which are notable for their completeness and accuracy.

DR. O. M. B. BULMAN, University lecturer in palæozoology, Cambridge, distinguished for his work on Lower Palæozoic stratigraphy, especially on the morphology, ontogeny and phylogeny of the Graptolites, and their geological history.

LORD CADMAN OF SILVERDALE, chairman of the Anglo-Iranian Oil Company, emeritus professor of mining and petroleum technology, University of Birmingham, distinguished for his many public services and for his leadership—administrative and scientific—in the development of the Iranian oilfields.

PROF. G. COOK, regius professor of civil engineering and mechanics, University of Glasgow, distinguished for researches into a wide variety of engineering problems and particularly for original investigations into the stress–strain relations of metals when passing from the elastic to the plastic state under systems of combined stresses.

DR. H. DAVENPORT, lecturer in mathematics, University of Manchester, distinguished for his work in pure mathematics and particularly for his contributions to the theory of numbers.

DR. C. F. GOODEVE, reader in physical chemistry, University College, London, distinguished for his work in many branches of physical chemistry and particularly for his contributions to our knowledge of absorption spectra and photo-chemistry.

PROF. F. G. GREGORY, professor of plant physiology, Imperial College, London, distinguished for his researches on the analysis of plant growth, especially in relation to mineral nutrition and vernalization.

PROF. A. C. HARDY, professor of zoology and oceanography, University College, Hull, distinguished for his researches on marine biology and their application to fishery problems, with special reference to the ecology of the herring and the distribution of plankton.

DR. C. H. KELLAWAY, director of the Hall Institute for Medical Research, Melbourne, Australia, distinguished for his researches on snake venoms and on protective antisera.

PROF. K. S. KRISHNAN, Mahendralal Sircar research professor of physics in Calcutta, distinguished for his researches in optics, and especially for his study of the influence of magnetism on crystals.

PROF. R. P. LINSTEAD, professor of organic chemistry in Harvard University, distinguished for work in synthetic organic chemistry, including reversible isomeric change, ring compounds and phthalocyanines.

PROF. O. MAASS, MacDonald professor of physical chemistry, McGill University, Montreal, distinguished for his researches in physical chemistry, particularly those relating to the properties of gases and liquids, during which he has detected and studied an important and anomalous behaviour in the critical region.

PROF. H. S. W. MASSEY, Goldsmid professor of mathematics, University College, London, distinguished for his work in mathematical physics and particularly for his contributions to the quantum theory and its applications to physics.

DR. B. H. C. MATTHEWS, assistant director of research, physiological laboratory, and fellow of King's College, Cambridge, distinguished for his work on electrophysiology, particularly in connexion with the sense organs and the spinal cord, by which important factors in the mechanism of the nervous system have been revealed.

PROF. W. H. PEARSALL, professor of botany, University of Sheffield, distinguished for his investigations on the determination of the factors underlying the distribution of aquatic plant communities, especially in the British lakes, and on the conditions affecting algal metabolism.

DR. J. H. QUASTEL, biochemist to the Cardiff City Mental Hospital, distinguished for his work on chemical reactions in resting bacteria, the mode of action of enzymes, the chemical metabolism of the brain, and the action of drugs.

PROF. A. ROBERTSON, professor of mechanical engineering, University of Bristol, distinguished for his fundamental contributions to knowledge relating to the stability and strength of solid and tubular struts, and to many other problems in the field of the strength of materials of engineering construction.

DR. L. F. SPATH, lecturer in geology at Birkbeck College, University of London, distinguished for his researches on the phylogeny of the Nautiloidea, the goniatites and the ammonites, and particularly on the problems of ontogeny and recapitulation in cephalopods.

DR. W. SUCKSMITH, reader in magnetism, University of Bristol, distinguished for his outstanding experimental researches, particularly on the gyromagnetic effect of paramagnetics and the physical properties of ferromagnetics.

NEWS AND VIEWS

Finland and the U.S.S.R.

HOSTILITIES between these countries have ceased, and a peace has been signed which gives the U.S.S.R. substantial territorial gains. Finland loses much of her industrial and agricultural areas by this treaty, and nearly half a million of her population are being transferred from the ceded territory to other parts of Finland. The country has suffered a grievous blow, not through any lack of valour, but through the overwhelming military power of the U.S.S.R. Now the Finns have turned with characteristic courage and energy to the task of reconstruction. Towns and houses destroyed by aerial bombardment have to be rebuilt, new towns created for the transferred people, and the whole of the economic life of the country has to be restarted under the new conditions, while the defence of the new frontiers must also be organized. The Finns have saved their freedom, and on this the nation will rise again. The help in men, money and materials still so sorely needed will surely not be grudged by right-thinking peoples who have watched the struggle of this gallant democracy.

Water Pollution Research

THE Department of Scientific and Industrial Research has opened a new Water Pollution Research Laboratory at Watford equipped for work on the problems of water supply, sanitation, and the recovery and utilization of valuable materials from trade effluents of many kinds. Plans for building a research station for work of this nature have been postponed by the War, but temporary accommodation has now been obtained. Although no central research station has hitherto been available for the work of the Water Pollution Research Board, many investigations have been carried out in the last few years, on behalf of the Board, in other laboratories. Among other important work, it has been shown that certain clays and glauconitic sands found in Great Britain yield material capable of softening hard water, and that certain synthetic resins can be used to remove dissolved salts and other substances from water.

The Board has also co-operated with industry in the investigation of river pollution by beet sugar and milk factory effluents. Another important investigation was that on the effect of the discharge of sewage into the estuary of the River Mersey on the deposition of silt and other solid matter in the estuary, and an investigation is now in progress at a branch laboratory in Birmingham, in co-operation with the Birmingham Tame and Rea District Drainage Board, which has indicated that the capacity of percolating filters for treating sewage can be increased by at least 50 per cent. Communications intended for the Director of Water Pollution Research should be addressed to the Water Pollution Research Laboratory, Langley Road, Watford, Hertfordshire.

Radioactive Standards

RELIABLE standards of weak radioactivity are required in a number of fields of work; for example, by geologists, geophysicists and cosmologists concerned with the radioactive content of the materials of the earth's crust; by biological and medical investigators employing the technique of radioactive indicators or internal artificial radioactivity therapy; and in studies of radium and thorium poisoning. A committee of the United States National Research Council is endeavouring to facilitate the needs of such workers by preparing a series of feebly radioactive standards which will be analysed at a number of laboratories equipped to make such measurements. These standards will ultimately be deposited at, and certified by, the National Bureau of Standards at Washington, D.C., to be issued as working standards to investigators who may desire them.

The standards in preparation are: (1) *Radium standards*, comprising 100 c.c. solutions in sealed flasks, for use as emanation standards; and 5 c.c. solutions in sealed ampoules for use as gamma-ray standards. (2) *Thorium standards* in the form of sealed ampoules containing sublimed thorium chloride for use in preparing standard thorium solutions. (3) *Standard rock samples* consisting of a variety of finely ground minerals of certified radium and thorium content, which may be used in fusion techniques for checking methods of extracting radon and thoron from rock samples.

Drug Addiction

IN a paper read at an evening meeting of the Pharmaceutical Society on March 12, Dr. Walter B. Kennedy, a member of the Poisons Board and formerly professor of physiology in the University of Baghdad, made some interesting references to the influence of habit-forming drugs brought to his notice in the Near East and elsewhere. A topical and important aspect of drug addiction is the problem of maruanha, the name by which the hemp plant, *Cannabis sativa*, is known in the United States. Maruanha, said Dr. Kennedy, is destructive of the moral sense: "Under its influence there develops a ruthlessness rarely encountered under other conditions, and a spurious courage, or rather a complete disregard for danger and consequences which results in horrible crimes of violence—often devoid of motive. An additional danger is that the addict is often led into indulgence in the white drugs, morphine, heroin and cocaine". Another exotic drug which has lately found its way to Europe is mescal or peyote, obtained from a Mexican cactus. It is an inebriant producing even more brilliant and prolonged hallucinations than does hashish.

Dr. Kennedy referred to the excessive use of endocrine products of which evidence was seen occasionally; he mentioned in this connexion the fashion which swept through a girls' school of taking thyroid for the purpose of securing lithe figures, a fashion which had serious results in several instances. There is a wide gap between maruanha and thyroid and a still wider one between the former and aspirin. "I may surprise some," said Dr. Kennedy, "if I refer to aspirin as a drug which gives rise to habit, and without being dogmatic I would merely give my opinion that it does". Another form of addiction, he said, was provided by certain medicated wines. Many people delude themselves with the idea that when a wine was 'medicated', it was somehow free from the stigma of what is picturesquely called the 'demon drink'. But there is no excuse for maruanha and no quarrel with the penalty which may be imposed in the State of New Jersey upon traffickers in this woeful drug, namely, thirty years imprisonment and a fine of ten thousand dollars.

Twenty-five Years of Transcontinental Telephony

IT is recalled in the *Laboratories Record* of the Bell Telephone System that on January 25, 1915, just twenty-five years ago, the first transcontinental telephone call was made across America and the east and west were united. President Woodrow Wilson talked from the White House across the country testifying to the nation's pride "that this vital cord should have been stretched across America as a sample of our energy and enterprise". The inventor of the telephone, Alexander Graham Bell, in New York, repeated across the continent to San Francisco the first words ever heard over a telephone, namely, his call to his assistant, "Mr. Watson, come here, I want you," to the same T. A. Watson who had heard them in the garret workshop in Boston in 1876. That ceremony ushered in transcontinental service twenty-five years ago. At that time it cost 20.70 dollars to call San Francisco from New York. Now it costs 6.50 dollars for a station to station call and only 4.25 dollars after seven in the evening and all day on Sunday. In 1915 it took about half an hour, on the average, to make a connexion ; now most calls are put through without 'hanging up'. The Bell System concludes by saying : "These are measures of progress in the never-ending effort of the Bell System to give faster, clearer, more useful and courteous service to the people of the United States".

Development of the Battery Vehicle

IN an article contributed to the *Electrical Review* of February 16, J. H. Cansdale states that during the last six years the number of battery vehicles has been rapidly increasing, and war-time conditions will most probably create a very much greater demand for them. In 1933, the number of battery vehicles registered in Great Britain and Northern Ireland was about 1,400, and it is estimated that the number at the beginning of this present year was about 6,500. Any service with short runs and frequent stops, particularly with loads between five and thirty cwt., is suitable for the battery vehicle. A large proportion of tradesmen's and similar services in towns and suburban districts comes within this category. The great advantages of the electric vehicle in lower running and maintenance costs are now augmented by the absence of restriction on the use of electric power for battery charging, in contrast with the present petrol restrictions.

The design of modern battery vehicles has been modelled closely on automobile practice. The weight of the battery necessitates a rather heavier frame, and special provision has to be made for accommodating the battery crates and for their easy inspection and removal. Four-wheel brakes are standard, and the drive to the back axle is by means of a propeller shaft with either a double-reduction bevel or worm gear. Pneumatic tyres of the medium pressure type have been found to give the best results by combining smooth running with economical power consumption. All the principal battery manufacturers now market special traction types able to withstand vibration and to provide heavy starting currents. Of the two principal types available, the lead-acid cell is most usually employed as its first cost is less than that of the alkaline battery. On the other hand, the latter has a life of about nine or ten years, whereas a lead-acid cell lasts only three or four, so that the difference in cost is levelled out. Owing to its higher internal resistance, the alkaline cell has a lower efficiency. For the small delivery van of the 12–15 cwt. class, the normal range of battery capacities is from 129 to 290 ampere hours. Capital costs are heavier than for an equivalent motor vehicle, but the life is approximately double, and both maintenance and running costs are considerably reduced.

Indian Sculpture and Architecture

THE Madras Government Museum has recently issued two publications, one of which is a guide to the archæological galleries of the Museum and is intended as an introduction to South Indian temple architecture and sculpture, while the second contains an illustrative series of photographic reproductions of examples of Indian sculpture, mostly southern, for use with the guide ("Guide to the Archæological Galleries". By Dr. F. H. Gravely and C. Sivaramamurti and other curators. Madras Government Press. Pp. v + 48 + 4 plates. 8 annas. "Illustrations of Indian Sculpture, mostly Southern, for use with the Guide to the Archæological Galleries". By Dr. F. H. Gravely and C. Sivaramamurti. Pp. ii + xlv plates. Rs. 1.8). In the introductory remarks anticipating the text of the Guide, the principle is laid down that "The display of museum collections to the public aims at fostering a deep and intelligent interest in the universe of which we form a part, especially our immediate surroundings", and it is added that the arrangement and display of this section of the Museum's exhibits have been attempted in such a way as to help visitors "to recognize for themselves the general affinities and probable period of temples and sculptures they see outside". With this praiseworthy objective, the authors sketch briefly the history of Indian art from the time of Asoka and in the centuries before our era down to the 'modern' period, with abundant references to the photographs and casts illustrating the Northern Schools, as well as to the actual exhibits from those of the South, special attention necessarily being directed to the Gupta period and Amaravarti.

No stronger plea than that afforded by these guides could be put forward for the adoption of a vigorous forward policy on the educational side throughout the museums of India. As the report of the Museums Commission showed, these institutions are already places of popular resort; but it depends upon the arrangement and administration of the museum itself whether they are mere repositories of 'curios', or really serve to bring home to the people the continuity in spiritual meaning underlying objects and buildings and structures familiar to them in their daily life. In the East, the function of the archæological museum is concerned with things of which the spirit, and sometimes, if not always, the form, is still alive.

Instructional Films in India

MR. C. F. STRICKLAND has recently published a paper on "Instructional Films in India" (*J. Roy. Soc. Arts*). They supply a ready means of education in a country which "it is not possible to make literate in the next ten years", though during that period instruction concerning good government must be acquired. Adults have to be educated and already Bengal is credited with 1,000 cinemas and 500 touring companies. But most of the films shown are non-Indian and 45 per cent of them are American. They are predominantly unsuited to Indian ideas and modes of thought. Indians do not think continually "in terms of sex emotion or crime". Some educational films are now made in India and several are on loan, but these are meant chiefly for the juvenile population. Mr. Strickland explained the requirements and limitations of the Indian adult, one of which is a pace much less rapid than that to which we are accustomed. This speed with perpetual excitement is, we note, quite unnatural, lacking the tension and relaxation which prevail in life and in the best stories of action, such as the "Three Musketeers". It is, in fact, the consequent strain on the mind which makes these pictures so easily forgotten.

Totaquina

IN a recent paper (*Asiatic Res.*, 35, 777; 1939), M. Ciuca states that in its search for an anti-malarial preparation cheaper than quinine but equally efficacious, the Malaria Commission of the League of Nations instituted research into the efficacy, compared with that of quinine, of a certain number of secondary alkaloid mixtures, such as kinetum, chineto, cinchona febrifuge, etc., used in the treatment of malaria in various countries. Research carried out in more than 4,000 patients in malarious countries proved that the efficacy of preparations containing 60–80 per cent crystallizable alkaloids including 15 per cent quinine was equal to that of quinine alone. The Commission has given the name of 'Totaquina' to a new preparation which is a mixture of cinchona bark alkaloids containing at least 75 per cent crystallizable alkaloids and not less than 15 per cent quinine. The advantage of the new preparation is a distinctly lower price, which is mainly due to the method of extraction, while its efficacy is equal to or only slightly less than that of quinine.

Seeing at Night

A PAPER by R. G. Hopkinson, of the Research Laboratories, General Electric Co., Ltd., published in the *Electrical Review* of March 1, on "Seeing at Night", shows that valuable progress has been made on this important subject during the last few years, especially in connexion with black-out conditions. Under weak illumination, the response of the eye is quite different from that under normal conditions. So far as light is gathered by the lens of the eye and is brought to a focus upon the retina, it functions like a camera, the retina acting like a photographic plate in recording the scene for the brain to interpret. The retina is provided, however, with two separate kinds of receptor nerve cells, the 'cones', which usually respond to bright scenes, and the 'rods', which respond to dark scenes. In daylight the cones only function. With bright artificial light both rods and cones are working, the rods recording the shadows and the cones recording the highlights for the brain. Under black-out conditions the rods alone are functioning.

Black-out vision is much inferior to day vision for the following reasons. (1) The rods do not record colours, hence black-out vision is devoid of colour sensation; all colours appear as varying grades of black and grey. (2) There are fewer rods per unit area of the retina than there are cones. The effect is analogous to that of a newspaper reproduction of a photograph, which is made up of a number of dots and is therefore less clear than the original. This handicap is the more serious since it is just that region of the retina which normally receives the clearest image, the fovea centralis, where the rods are fewest. Hence, as many must have noticed at low illuminations, vision is often better around the periphery of the eye.

New Commercial Fruits in the United States

O. ATKINS writes in the *American Fruit Grower* (Dec. 1939) on the utility of the wild dryland blueberry (*Vaccinium vaccillans* Kalm) in relation to soil conservation. Experiments have shown that it has unusual erosion-resistant qualities on account of its underground shoots, which send out a mass of fine roots and bind the soil together over a large area. In addition to this useful property, the blue-black fruits promise to form a successful commercial crop, and as the plant will grow and fruit in partial shade or full sunlight it is well suited to 'hill-culture'. A systematic breeding programme is being undertaken by the U.S. Department of Agriculture and Soil Conservation Service.

The papaya (*Caprica papaya* L.), according to S. J. Lynch, writing in the same journal, is now being grown commercially in South Florida. The texture of the flesh is similar to that of a cantaloupe, yellow to reddish-orange in colour, with a sweet musky flavour. The fruits, which vary in size from a few ounces to 25 lb. in weight, contain 5–6 per cent of sugar, no starch, and appreciable amounts of vitamins A, B and C. The proteolytic enzyme papain, which also occurs in the fruit, is used in many commercial products as an aid to digestion. Numerous food and drink products are being made from the fruit pulp. The plant will bear for three or four years, but is treated commercially as an annual, since the finest fruit is obtained in the first year. Both monœcious and diœcious plants occur, which makes standardization difficult; but breeding work is being carried out to establish uniform strains.

Poultry Rations in War-time

COMMERCIAL poultry-rearing has reached a high state of efficiency, and part of that efficiency is expressed in a standardized ration, in which only food ingredients are used which have been proved to be best suited for their purpose. Under war conditions the accustomed standardized ration must be given up, since the amount and nature of feeding stuffs available for livestock becomes restricted, partly because of a reduction in imported supplies and partly because of the wider use of home-grown cereals for human consumption. Poultry-keepers are urged to exercise the greatest economy in the use of such imported materials as maize, and in order that the accustomed ration may be replaced by satisfactory substitutes the Ministry of Agriculture and Fisheries has issued, as one of its "Growmore" Leaflets (No. 14), a summary account of materials which may be used in rearing, growing or breeding rations. The list includes thirty-one different food materials, and the feeding value and method of using each stuff is stated briefly. Single copies of the leaflet—"Poultry Rations in War Time"—may be obtained free of charge and post paid on application to the Secretary, Ministry of Agriculture and Fisheries, 10 Whitehall Place, London, S.W.1.

Birds of the Fenland

CHANGES in the kind and distribution of the animals of the countryside which have been brought about by the progress of civilization are greater than is generally supposed, although often they are difficult to trace in detail. A short account of such changes as they have affected birds in the Fenland appears in the winter issue of *Bird Notes and News* (p. 198), the journal of the Royal Society for the Protection of Birds. In it Francis E. R. Peach, having quoted some early references to the bird-life, compares the earlier fauna with that of the present day, and shows that the general trend in the Fen area has been in the direction of a decline in ducks, geese, waders and birds of prey as drainage proceeded, and an increase in small birds such as linnets, yellow buntings and skylarks which now occupy the reclaimed marsh lands. Surely it is an omission that in dealing with the bird-history of this region the author does not refer to the invaluable "Early Annals of Ornithology", by the late J. H. Gurney, himself a Norfolk man.

Dutch Biology

A. VAN LEEUWENHOEK is known to every biologist as the name of a most eminent Dutch man of science, but we doubt whether many know that it is also the name of a worthy journal of Dutch microbiology, in spite of the fact that five volumes of it have already been published. This is in large measure due to its having appeared in the Dutch language, which has prevented its being read by more than a few English workers. We are glad to welcome its appearance in a new form. The editors and the Board of the Netherlands Society of Microbiology who are responsible for it have appreciated this difficulty, and from volume 6, No. 1, January 1940, it appears under the title *Antonie van Leeuwenhoek, Journal of Microbiology and Serology*, with English, French and German as the official languages. Thus the present number contains seven papers, five in English, one in French and one in German. Its pages are thrown open to workers of any nationality, and the editors hope that, in spite of the present inauspicious conditions, it will serve a wider public.

Demography of England and Wales

IN the third quarter of 1939, 161,201 live births were registered, or 3,119 more than the number recorded in the corresponding quarter of 1938. Of the total 6,458 were illegitimate, or 13 less than in the third quarter of 1938. The deaths numbered 103,170, and were 17,263 less than in the preceding quarter, but 568 more than in the third quarter of 1938. The mortality of infants under one year of age was equal to 39 per thousand registered live births. This rate is 8 per thousand below the average of the ten preceding third quarters and is the lowest quarterly rate ever recorded. The number of persons married in the third quarter of 1939 was 304,716, an increase of 72,084 on the number in the corresponding quarter of 1938. This number corresponds to an annual rate of 29·3 per thousand of the estimated mid-year population for 1938, and is the highest rate yet recorded.

X-Ray Photography of the Renal System

In order that X-ray photographs of the renal pelvis and ureters may be obtained, it is necessary to employ a substance which, after injection into the veins, is excreted by the kidneys and is opaque to the rays, so that a shadow picture of the excretory apparatus of the kidneys may be obtained; further, such a substance must have no harmful effect. A new preparation has been introduced by Glaxo Laboratories, Ltd., under the name of "Pyelectan", which it is stated possesses the necessary properties in marked degree. Chemically, it is the sodium salt of a complex iodine-containing dicarboxylic acid, the iodine content being 51·5 per cent. Pyelectan is claimed to have a low toxicity and to be generally well tolerated, rapidly excreted by the kidneys and yielding a dense and well-defined shadow in the renal pelvis and ureter.

Science Abstracts

THE reduction in thickness of the monthly issues of *Science Abstracts* during the last few months of 1939 will have prepared readers for a reduction of the number of abstracts in the volumes now completed for the year. Section A (Physics) contains 4,725 abstracts, a reduction of 7 per cent on the volume for 1938, and Section B (Electrical Engineering) 2,811, a very noticeable reduction of 22 per cent. Both have established for themselves international reputations as reliable records of yearly progress in the sciences with which they deal, and as indispensable to those who would keep themselves up to date.

Parliamentary and Scientific Committee

THE Earl of Dudley has been re-elected president of the Parliamentary and Scientific Committee for the year 1940. The other officers elected are: *Vice-President*, Captain S. F. Markham, M.P.; *Chairman*, Captain L. F. Plugge, M.P.; *Vice-Chairman*, Prof. B. W. Holman; *Deputy Chairman*, Mr. E. W. Salt, M.P. The Committee has recently had under consideration the question of the release from military service of certain skilled technicians and scientific workers for other work of vital national importance, and also the question of suitable employment being given to technical and scientific workers who have enrolled for military service. At the next meeting of the Executive Committee of this body the question of the collection and utilization of town refuse and waste products will be considered.

Earthquakes during February 1940

AT Kew, Basle, Chur, Zurich and Neuchâtel the registrations of earthquakes tended to show that the earth was seismologically less active than normal during February 1940. At Kew only ten notable shocks were registered during the whole month, the greatest being the three of February 7, 20, and 29. At the Swiss observatories, seventeen shocks were registered, though only nine sets of readings were sufficiently clear to obtain epicentral distances, two of these being doubtful. Distant earthquakes giving consistent readings were those of February 7, 23, and 29, the four others being much nearer to the Swiss stations. Fairly good readings were obtained at Kew for the earthquake of February 23 and at the Swiss observatories for that of February 20, but epicentral distances were not determined.

The greatest earthquakes during the month thus appear to have been those of February 7 and 29. The former, according to the United States Coast and Geodetic Survey in co-operation with Science Service and the Jesuit Seismological Association, on the basis of reports from seventeen stations, had its epicentre near lat. 52° N., long. 174·5° E., and its initial time 17h. 15m. 56s. G.C.T., with normal depth of focus. This point is immediately to the south-east of Near Island in the Aleutian Islands group and close to the undersea escarpment, where the depth of sea quickly falls to more than seven thousand metres, according to the U.S. Geographical Society map. Although the Aleutian Islands are known to lie along a seismic belt, the region appears to have been more than normally active since the 'missing' earthquake of November 10, 1938. The earthquake of February 29, according to the Zurich seismologists, had its epicentre near lat. 45° N., long. 27° E., which is in Rumania, approximately midway between Bucharest and Galati. On the same authority the earthquake just after 1 a.m. on February 9 had its epicentre near Mont Blanc, and the earthquake of February 23 in Albania. All the above epicentral determinations are tentative.

Announcements

DR. L. E. H. WHITBY has been awarded the John Hunter Medal and Triennial Prize of the Royal College of Surgeons for his research work in "Bacteriology with special reference to the Sulphonamide Compounds".

THE office of the Royal Society has now returned to the Society's apartments in Burlington House and the library is re-opened. Communications, therefore, should be directed to the Royal Society, Burlington House, London, W.1.

THE British Association announces that the grounds of Down House, Charles Darwin's home at Downe, Kent, will be open to the public free of charge from Good Friday onward, from 10 a.m. to 6 p.m.

THE sixth Australian Medical Congress, which was to have been held at Perth, Western Australia, during September 2–7, 1940, has been postponed indefinitely.

THE herbarium of indigenous medicinal plants which is being collected at Calcutta under the ægis of the School of Tropical Medicine now contains 1,500 species, or approximately 5,000 specimens. It is hoped that when the herbarium is completed it will comprise specimens of all the 2,500 medicinal plants known to be growing in India.

DURING the first six months of 1939, 313,226 marriages took place in the old German Reich, or 10,122 (3·3 per cent) more than in the corresponding period of 1938 (303,104). In the second quarter of 1939 there were 11·2 marriages for every 1,000 inhabitants. In the same period there was a remarkable rise in the number of marriages in the former Austria, namely 28,490, or 8,921 (45·6 per cent) more than in the corresponding period of 1938. In the first half of 1939 there were 59,210 marriages in the former Austria, or 28,954 (95·7 per cent) more than in the corresponding period of 1938 (30,256).

ERRATUM.—Dr. Julian Huxley points out that the title of the substance of his British and American Association Lecture published in NATURE of March 2, p. 330, should have been "Science, War and Reconstruction".

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

IN THE PRESENT CIRCUMSTANCES, PROOFS OF "LETTERS" WILL NOT BE SUBMITTED TO CORRESPONDENTS OUTSIDE GREAT BRITAIN.

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 466. CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Production of Synthetic Mycorrhiza in the Cultivated Cranberry

UNDER this title, Bain[1] describes experimental investigations on mycorrhizal relationships in *Vaccinium macrocarpon*, Ait., *V. canadense*, Kalm., and two ericaceous species, reviewing and criticizing the conclusions of earlier observers in the light of his own results. In so far as the latter relate to *Vaccinium macrocarpon*, they may be summarized as follows. A fungus, specifically distinct from those associated with the other species studied, was isolated from roots of the cranberry, *Vaccinium macrocarpon*. Identity of this fungus with that forming mycorrhizal complexes in the root cells of the host was established by inoculation of the mycelium into pure cultures of cranberry seedlings growing in nutrient agar and in 'artificial soil' composed of cork and sand.

Bain describes the colonies and mycelium of this fungus as 'specifically distinct' from those isolated by him from the other species investigated, and also from those of *Phoma radicis callunæ* obtained from the Centralbureau voor Schimmel Cultures in Baarn. Its affinities and systematic position have not been determined.

Designation and acceptance of *Phoma radicis* as the mycorrhizal associate of Vaccinium spp. and members of Ericaceæ rest on the following evidence. In 1907, Ternetz[2] reported the isolation of distinct strains of what was regarded as a single fungus species from roots of a number of native ericaceous species and from *Vaccinium Oxycoccus* and *V. Myrtillus*, all growing in Switzerland. Sporing cultures of all these fungi were submitted to Lindau and Hennings in Berlin for identification and were referred by them to the genus Phoma as a new species under the name *P. radicis*. The form associated with the European cranberry, *Vaccinium Oxycoccus*, like the others, was distinguished in culture by definite characters relating especially to the numbers of pycnidia produced, manner of fruiting, and size and shape of pycnidia and spores.

In 1915, one of us[3] reported the isolation from seeds of *Calluna vulgaris* of a fungus identical in all respects with the form of *P. radicis* described by Ternetz as the mycorrhizal associate of this plant. Subsequent observations on *Vaccinium Oxycoccus* and *V. macrocarpon* were concerned only with systemic infection of the vegetative parts and seeds; isolation of the root fungus was not attempted in either species of Vaccinium. It was tacitly assumed in this paper on Vaccinium that the mycorrhizal fungus present in roots of the native cranberry, *V. Oxycoccus*, was *Phoma radicis Oxycocci* as described by Ternetz for this species in Switzerland, and this assumption was extended to the closely similar N. American species, *V. macrocarpon*, simultaneously under observation.

Although Bain's results do not necessarily constitute a direct challenge, they introduce uncertainty, as to the correctness of Ternetz's conclusions in respect to the identity of the mycorrhizal associate of *V. Oxycoccus*, and to the validity of the subsequent tacit acceptance of this view and its extension to *V. macrocarpon*; it was evident from study of Bain's paper that a re-investigation of this matter on British material of *V. Oxycoccus* was desirable. The results of such investigation are hereby placed on record.

Freshly lifted roots of *V. Oxycoccus* were washed in running water, sterilized by immersion in 1 per cent hydrochloric acid or 0·01 per cent mercuric chloride for 15–20 seconds, and rinsed repeatedly in sterilized water. Small pieces of roots so treated were then transferred to tubes of various media, including that used by Ternetz. A majority of these platings developed pure culture colonies of greyish white mycelium, becoming pinkish brown to dark brown with age. After two to three weeks growth at room temperature, these colonies fruited, forming pycnidia of various sizes in and upon the substrate. In all respects—character of colonies and mycelium, numbers and mode of formation of pycnidia, and size and characteristics of pycnidia and pycnidiospores—this fungus resembles *Phoma radicis Oxycocci* as described by Ternetz.

We are greatly indebted to Dr. J. Ramsbottom, keeper of botany, British Museum (Natural History), for examining our cultures and confirming the identity of the root fungus isolated by us with that extracted by Ternetz from Swiss material of *V. Oxycoccus*. A similar investigation is in progress on garden material of *V. macrocarpon*.

It may be added that root material treated as described by Bain, by repeated washings in distilled water without surface sterilization, gave rise in all cases observed by us to colonies of unidentified fungi, usually yellow or orange in colour.

Full discussion of Bain's conclusions in respect to this matter and to his views respecting the nature of the mycorrhizal associations in Ericaceæ must await a convenient occasion. In justice to the pioneer observations of Ternetz, it is desired to place on record these relating to the cranberry fungus as soon as possible.

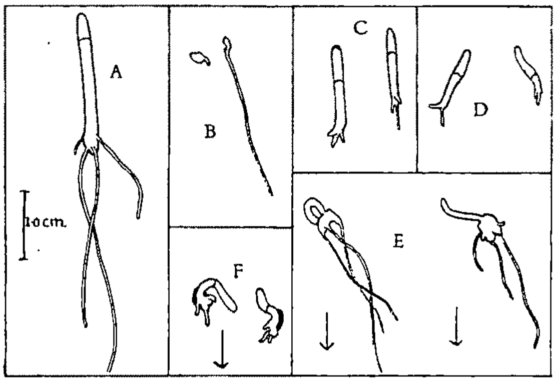
Vernalization of Fragments of Embryo Tissue

EMBRYOS of cereal grains, separated from the endosperm and cultured on a medium containing sugar, can be vernalized by exposure to a temperature of 1° C. in the same way as whole grains[1,2,3,4]. In order to locate more precisely the tissues concerned in the process, embryos of Petkus winter rye were mutilated in various ways before vernalization treatment. In this preliminary experiment only two embryos were subjected to each type of mutilation.

Treatment	No. of replicates	Condition of plants 84 days after end of treatment
A. *Vernalized* 6 *weeks*		
1. Whole embryos	7	All past anthesis.
2. Stem apex and fourth leaf retained	2	Both with ears emerged.
3. Scutellum removed	2	One vegetative, one shooting.
4. Scutellum and shoot apex removed	2	No plants obtained.
5. Scutellum and roots removed	2	One with ear emerged, one shooting.
6. Scutellum and coleoptile removed	2	One with ear emerged, one vegetative.
B. *Vernalized* 2 *weeks*		
1. Whole embryos	14	All vegetative.

The fragments were planted on agar medium containing 2 per cent sucrose, vernalized at 1° C. for six weeks, and after eight further days growth on the medium at a temperature of approximately 18° C., were large enough to be planted out. The appearance of the fragments at the end of the vernalization period is shown in the figure. The removal of the coleoptile has the curious effect of promoting hypertrophy of the tissue about the roots, and there is, in addition, a lack of gravity perception in the first leaf. Possibly the latter effect is simply due to the absence of the mechanical support of the coleoptile, but it is interesting to note that whole embryos, germinated on 2 per cent sucrose with the addition of 1/10,000 hetero-auxin solution, show a similar failure of gravitational response as well as the hypertrophy of the coleorrhiza (see accompanying figure, *F*).



CAMERA LUCIDA DRAWINGS OF EMBRYO FRAGMENTS AT END OF SIX WEEKS VERNALIZATION AT 1° C. *A*, COMPLETE EMBRYO ; *B*, STEM APEX AND FOURTH LEAF INITIAL ; *C*, SCUTELLUM REMOVED ; *D*, SCUTELLUM AND ROOTS REMOVED ; *E*, SCUTELLUM AND COLEOPTILE REMOVED ; *F*, COMPLETE EMBRYOS GROWN FOR SIX WEEKS AT 1° C. ON MEDIUM CONTAINING 1/10,000 HETERO-AUXIN (FOR COMPARISON WITH *E*. IN *E* AND *F* THE ARROW INDICATES THE DIRECTION OF THE GRAVITATIONAL PULL).

Only those embryos from which the stem apex had been removed failed to produce green plants, but their roots continued growth in the sucrose medium for many weeks. Plants arising from the isolated stem apex were dwarfed ; each consisted of a main stem and one tiller, and in one the main axis bore an ear on a stem about four inches high, with six leaves. The progress towards flowering made by each plant during 84 days from the end of vernalization is shown in the table ; no further observations were made. Comparison with plants grown from embryos vernalized for two weeks makes it clear that vernalization treatment has accelerated flowering but that the process was less effective than in the case of complete embryos.

Permeability of Insect Cuticle

ONE of the major problems in research on insecticidal action concerns the correlation of the toxicity of an insecticide with its chemical and physical properties. Very little progress has hitherto been made when relatively non-toxic carriers have been used. This is mainly due to the fact that too little physiological significance has been attached to the mode of action of the carriers in relation to the toxic principle under investigation.

A study of the toxicities of various constituents of heavy naphtha to the nymphal and adult stages of the bed-bug, *Cimex lectularius*, L., has shown that the toxicity of unsaturated compounds, such as indene, may be materially increased by the addition of non-toxic mixtures of paraffins and cycloparaffins. The assumption that the unsaturated compound was assisted through the cuticle by the more apolar substances present in heavy naphtha led to an investigation of the general physiology and permeability of the insect cuticle. The results show that feebly dissociating compounds of high dielectric constant penetrate the cuticle much more readily in the presence of relatively apolar substances of low dielectric constant, the main region of induced penetration being at the cuticle-hæmolymph interface. This generalization applies both to fumigant and contact action, and may be conveniently illustrated by a model experiment, using as test insects, larvæ of the blowfly, *Calliphora erythrocephala*, Meig.

When a larva is immersed in ethyl alcohol, penetration through the cuticle and tracheal system takes place very slowly, and the insect generally remains active for at least an hour. The effect of paraffins of the kerosene type is even less pronounced, and loss of reaction to a mechanical stimulus may take two hours or more. With a mixture of ethyl alcohol and paraffins, penetration of the alcohol is so rapid that the insect dies within a few seconds, swells perceptibly, and eventually bursts within four to six minutes. A peculiar swirling effect is noticeable in the region of the cuticle, which is due to the passage of water from the insect. This results in the paraffins being thrown out of solution in the immediate vicinity of the insect, and finally leads to a partial separation of the two components throughout the whole volume of the liquid, the degree of separation depending on their relative proportions in the mixture. Mechanical blockage of the spiracles does not materially affect the nature of the results.

The mechanism of penetration has been studied for the cuticles of several species of insects, and an account of this work, together with various insecticidal applications, will be published in due course.

There are two primary layers in the insect cuticle: an inner chitin layer, which consists essentially of a mixture of chitin and protein, and a thin outer lipoid layer. The present work has shown that this outer layer is relatively impermeable to polar compounds such as ethyl alcohol and acetic acid. The chitinous layer, however, is relatively permeable to both polar and apolar compounds, depending on the type of compound and the particular nature of the cuticle. The permeability of the lipoid layer to polar compounds is greatly increased by the presence of apolar substances. Thus, when a mixture of ethyl alcohol and paraffins is applied to the cuticle, the polar compound will penetrate the outer lipoid layer and then diffuse into the insect through the chitinous layer, the rate and extent of this diffusion being more pronounced than the diffusion of water in the reverse direction. In experiments on Calliphora larvæ, the insects burst before equilibrium was attained. With any particular mixture, the diffusion is governed by mutual solubilities and the pathological changes occurring in the various tissues. The permeability of the cuticle as a whole to polar compounds is increased in *both* directions by the presence of apolar substances. This increase is more pronounced in the direction lipoid layer – chitin layer, than in the opposite direction.

The relation between polarity and induced penetration of one or more substances has been worked out for a large number of compounds, and applies generally to polar substances of feebly dissociating properties, such as alcohols, fatty acids, phenols, nitrogen heterocyclic bases, ammonia, and hydrogen cyanide. Induced penetration appears to be negligible for such strongly dissociating compounds as neutral salts and mineral acids.

The results obtained are in agreement with the work of Alexandrov[1] and Morozov[2] on the permeability of the insect cuticle to various substances acting *singly*. The present work shows a close analogy with the work of Yonge[3] on the permeability of the integument lining the foregut of the decapod crustacean Homarus. So far as can be ascertained, no mechanism for induced penetration has previously been suggested. Fulton and Howard[4] have shown by injection methods that the toxicity of derris inside the insect may vary with the nature of the oil carrier used. This may be correlated with Yonge's suggestion that the permeability of the integument in the Crustacea shows a close resemblance to the permeability of the membrane of the living cell.

Bliss[5] has recently discussed the action of two poisons jointly, and has devised a classification based on relative toxicities of mixtures determined at several dosages. The present work shows that the carriers of the poisons cannot be neglected and that each constituent of a mixture may contribute to the toxicity of the whole even though it may, by itself, have no obvious toxic effect.

This statement is based on work begun under the ægis of the Medical Research Council Bed-bug Committee. Its extension is being carried out by means of a grant made to the Imperial College by the Department of Scientific and Industrial Research. I am especially indebted to Dr. N. F. Sarsfield for his assistance on the chemical side of the work.

Chronological Sex-Ratios in Drosophila

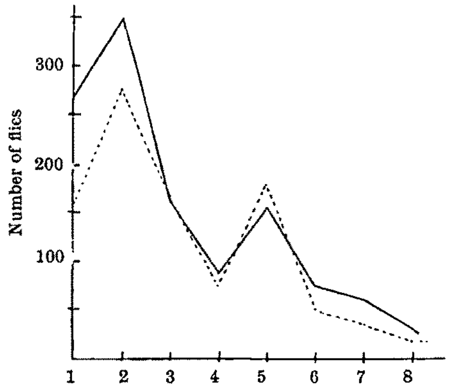
ANALYSIS of the results of observations on *Drosophila melanogaster* involving several thousands of flies substantiated previous observations in connexion with the daily variation in emerging frequency of males and females respectively of the criss-cross generation involving the sex-linked genes *y* and *w*.

Generally, cultures in which the parents were kept for forty-eight hours yielded mostly females on the first and second days of emerging. But on the fourth day of emerging the sexes evened up in numbers and on the fifth day the males outnumbered the females, the sex-ratio dropping below 50 per cent in favour of the males. The respective percentages of the total of females emerged for the first and the following seven or eight days (that is, until the culture is exhausted) were found to be approximately 30; 23; 15; 10·3; 12; 6·4; 0·5; 2; etc. The corresponding percentages of the total of males emerging were 15·7; 18·5; 15·7; 13; 24; 8·1; 2·8; 2·2; etc. (The chronological female percentages (sex-ratios) were: 68; 58; 51·5; 49·4; 36·1; 46·9; 18·2; etc.)

From these percentages it will be seen that 53 per cent of all the females and only 34 per cent of all the males emerged during the first two days. Also it will be seen that the highest percentage, namely, 24 per cent, of all males was realized on the fifth day of emerging, when the males outnumber the females. The second highest daily count of males was obtained on the second day of emerging, namely, 18·5 per cent of the total number of males. After the fifth day of emerging there was a relatively sharp decline in the number of flies emerging, reaching its lowest point on the seventh day. On the eighth day a slight arrest in this decrease was seen. From the fourth to the seventh day the males outnumbered the females. The female figures also showed a slight rise in numbers emerging on the fifth day, while an arrest in decrease seemed to occur on the eighth day of emerging.

Observations on similar lines were made on the mutant stock yellow body colour (*y*), white eyes (*w*) (see accompanying illustration). The daily percentages of the totals of emerged females and males respectively were: 22·5; 29·1; 13·6; 7·2; 13·8;

6·2; 5·0; 2·5; etc., and 16·8; 28·8; 17·2; 7·7; 18·6; 5·0; 3·7; 1·7; etc. Here the female curve also showed a high peak on the second day and another but slightly lower peak on the fifth day of emerging. This fifth day female peak was much more pronounced than that of the criss-cross generation mentioned above. The difference between the number of females and males for the fifth day was consequently not so large as in the case of the criss-cross generation.



Consecutive days of emerging
D. melanogaster (*y-w* stock)
——— ♀♀, - - - - ♂♂, n = 2143

Data treated on similar lines and obtained from observations on *Drosophila melanogaster* (wild) and *Drosophila simulans* (wild) showed a pronounced second day peak for both sexes but no fifth day peak. Hereafter there was an unarrested decline. The females were in the majority, more or less to the same degree for every day of emerging. The daily percentages of the total of females and males respectively for *Drosophila melanogaster* were: 28·7; 40·9; 19·5; 9·2; 1·1; 0·27; 0·27; and 22·8; 35·7; 26·0; 12·5; 0·6; 0·3; etc. The corresponding percentages for *Drosophila simulans* were: 18·6; 32·3; 15·7; 13·2; 8·4; 5·7; 2·8; 1·9; etc., and 11·4; 35·8; 20·0; 14·3; 8·6; 3·9; 2·6; 2·6; etc.

It is important to note that especially for the criss-cross generations involving the sex-linked genes *y* and *w*, and probably also other sex-linked genes, the sex-ratio may be inherently different from the first to the last day of emerging.

The percentage of females for the consecutive days of emerging of the criss-cross generation were: 68; 58; 51·5; 49·4; 36·1; 46·9; 18·7; 55·1; etc., the average being approximately 51·6.

Chromosome Numbers in *Sclerostachya fusca*

Sclerostachya fusca A. Camus (*Saccharum fuscum* Roxb.) is a grass closely related to *Saccharum spontaneum* and similar to it in habit. It is distinguished from Saccharum by its rachis being tough instead of fragile and by its pedicelled spikelets being female instead of hermaphrodite. (The sessile spikelets in both are hermaphrodite.)

This grass grows in association with *Saccharum spontaneum* in Assam and Orissa. I collected several clones from both these localities in 1937. The peasants use it extensively for roofing and making framework for their mud houses, as well as for fencing. It goes by the names of *yekkada* and *ikra* in these provinces.

The Orissa form proved to have 48 chromosomes, and the Assam form, which was of larger habit, had 96 chromosomes.

Most of the Andropogoneæ, including *Saccharum officinarum*, have 10 as their basic number. Exceptions to this are Miscanthus with 36 chromosomes and the dibasic *Saccharum spontaneum* in which forms with $x = 6$ and $x = 10$ have been found.

The doubling within the species is analogous to the condition of *Saccharum spontaneum* with its west-to-east transition from 48 to 112 chromosomes[1]. The discovery of another genus, more closely related to Saccharum than Miscanthus, with the basic number of 6, makes it easier to understand the origin of the dibasic cultivated sugar canes.

Amœba lescheri (= *Chaos lescheri*): a New Species of Amœba

EARLY in 1938 I discovered a new species of Chaos (better known as Amœba in Great Britain) which I propose to name *Chaos lescheri* = *Amœba lescheri*, to honour the memory of Mary Adela Lescher, founder of Notre Dame College, Glasgow. A full account of the life-history of this amœba will appear in the *Quarterly Journal of Microscopical Science*. The amœbæ of the genus Chaos are large and form pseudopodia that are sub-cylindrical, blunt and filled with granular endoplasm throughout. Conspicuous longitudinal ridges and grooves are characteristic of the ectoplasm. *Amœba lescheri* is readily distinguished from the other species of Chaos by its crystals, which are square prisms (maximum size 2 μ). Outsized spherical individuals attain a diameter of 525 μ, creeping individuals a length of 600 μ. The average for the former is 350 μ and for the latter 400–500 μ.

Translucency in amœbæ is a factor of age and physiological condition, depending to a large extent on the cytoplasmic inclusions. Having regard to these considerations, *Amœba lescheri* is more translucent, as it is also slightly smaller than *A. proteus* Y[1]. The shapes assumed by the contrasting amœbæ also differ, more of the bulk of the cytoplasm being concentrated in the pseudopodia of *A. lescheri*. Normally there is present one nucleus, discoid in shape. Alternate aspects of the nucleus, 'plan and elevation', are presented to the observer as the nucleus is subjected to the streaming movements of the endoplasm. Frequently the nucleus has the appearance of a biconcave lens. Since it normally lies in the peripheral endoplasm it is quickly found in a microscopical preparation of the living animal. The chromatin is distributed on an achromatic network and takes the form of regularly arranged blocks under the nuclear membrane distinct from, and slightly separated from, the rest of the network where the chromatin is not so regularly distributed.

There is one contractile vacuole (42 μ) which empties very deliberately after having moved to the posterior end. Nutritive spheres vary in size from 1 μ to 7 μ, depending on the age of the amœba, which feeds voraciously on ciliates, flagellates and rotifers. Excreta, including crystals, are gathered into a large vacuole in which a violent commotion is set up, the contents being shot explosively out of the vacuole.

A. lescheri has a marked tendency to send its pseudopodia in all directions even when more or less imprisoned under a cover slip. After having gripped the substratum and moved definitely in one direction on one, two or three pseudopodia, it loosens itself by forming radial pseudopodia and floats about. It may later return to the creeping position.

Fission of the cytoplasm may easily be observed. Spherical individuals are often binucleate. Two daughter sets of pseudopodia formed on one such floating binucleate individual indicate the onset of fission. The two daughter amœbæ use the floating debris to separate themselves as they float away. There is no thin connecting strand of protoplasm—the break is clean-cut. Under favourable conditions of environment *A. lescheri* divides once in twenty-four hours and is a good subject for 'pure-line' experiments.

One of us (Sr. C.) has investigated the cytology of the nucleus. In contrast to *A. proteus* Y. the number of nuclei never exceeds two. The average diameter is 42 μ. There is great diversity in the size of the chromatin blocks where the chromatin is more voluminous and not so immeshed in achromatic network as in *A. proteus* Y. Division in the nucleus is *amitotic*.

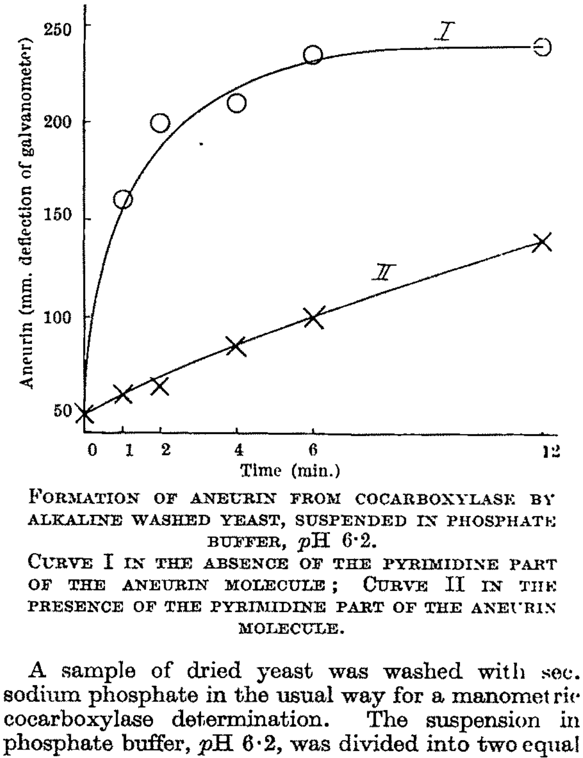
Cause of the 'Activation' of the Carboxylase System by Free Aneurin

ABOUT two years ago, Ochoa[1] made the remarkable discovery that decarboxylation of pyruvic acid by alkaline washed yeast, Mg^{++}-ions and cocarboxylase is stimulated by pure aneurin and by some derivatives of the pyrimidine part of the aneurin molecule. We have now discovered the mechanism of this stimulating action by performing some aneurin and cocarboxylase determinations by means of the thiochrome method[2]. All experiments have been carried out with baker's yeast, dried at 25° C., supplied by Distillers Co., Ltd., Epsom, with which aneurin exhibits a strong effect as compared to many other yeasts[3].

When aneurin and cocarboxylase are determined about one minute after adding cocarboxylase to a suspension of alkaline washed yeast in phosphate buffer, *p*H 6·2, a considerable part of the quantity of cocarboxylase added appears to have been converted into aneurin already. The amount of aneurin still increases rapidly during the first minutes after incubating the suspension in a bath at 28° C. From these findings some conclusions could be drawn: (1) a phosphatase, very active at *p*H 6·2, is present in alkaline washed yeast; (2) no experiment performed with this yeast, to which cocarboxylase was added, has been carried out in the absence of free aneurin; (3) the amount of cocarboxylase really acting is always much smaller than the amount added and supposed to act. These results led us to the hypothesis that Ochoa's aneurin effect might be caused by the inhibition of the phosphatase action by aneurin, namely, one of the reaction products of cocarboxylase hydrolysis. So the aneurin would not actually stimulate the carboxylase system, but only inhibit a reaction destroying cocarboxylase.

The following experiment has fully confirmed this hypothesis. As we met with some difficulties concerning the thiochrome method, when it was applied to a very large amount of aneurin in proportion to the amount of cocarboxylase present, this experiment was carried out with 2-methyl-4-aminopyrimidyl-5-methylaminodihydrochloride instead of aneurin.



FORMATION OF ANEURIN FROM COCARBOXYLASE BY ALKALINE WASHED YEAST, SUSPENDED IN PHOSPHATE BUFFER, *p*H 6·2.
CURVE I IN THE ABSENCE OF THE PYRIMIDINE PART OF THE ANEURIN MOLECULE; CURVE II IN THE PRESENCE OF THE PYRIMIDINE PART OF THE ANEURIN MOLECULE.

A sample of dried yeast was washed with sec. sodium phosphate in the usual way for a manometric cocarboxylase determination. The suspension in phosphate buffer, *p*H 6·2, was divided into two equal parts. One of these parts was supplemented with an amount of 2-methyl-4-aminopyrimidyl-5-methylaminodihydrochloride, giving maximal 'activation' (200 γ per 100 mgm. yeast), and both parts were allowed to react with cocarboxylase (5 γ per 100 mgm. yeast). Aneurin and cocarboxylase were determined at the times plotted in the accompanying graph. These curves, showing the velocity with which aneurin is formed, clearly demonstrate the inhibiting effect of the pyrimidine derivative on the phosphatase action. The curves showing the velocity of the decrease of the quantity of cocarboxylase are exactly the mirror-images of the curves of the accompanying graph; they are omitted to save space.

We believe we can explain all observations concerning the influence of aneurin on the carboxylase system from the point of view developed here; for example, the different sensitivity to aneurin of different kinds of washed yeast[3] (different amounts of phosphatase); the influence of the temperature of the phosphate solution used for washing the yeast[3] (destruction of phosphatase at higher temperature); Lipmann's observation[4], fully confirmed in this laboratory by Mr. Eitje and Mr. Hiegentlich, that aneurin is without any effect, when it is added to the yeast suspension some minutes after the addition of cocarboxylase (cocarboxylase destroyed already before the inhibition of phosphatase by aneurin); no stimulating effect of aneurin observable with Weil-Malherbe's purified carboxylase[5] (absence of phosphatase).

We wish to thank Prof. B. C. P. Jansen for his kind interest in our work.

Chalk Landscape

GEOLOGISTS used to ask themselves a riddle: How did the rounded outlines of the chalk denes and downs come to show the forms characteristic of sculpture by streams, since water runs straight through the chalk and does not form streams upon it? The acceptable answer to the riddle used to be that long ago the chalk below the surface was made impermeable summer and winter by frost, and that in the spring the snows of winter rushed off the frozen surface in torrents. Weather conditions last winter in our part of Wiltshire illustrated this strikingly in a way which the oldest inhabitant does not remember to have seen before. My house is in a dene in the chalk sloping gently to the Kennet for nearly two miles, with downs on each side. It will be remembered that there was first sharp frost with heavy snow-falls, then a few days thaw, and then again sharp and prolonged frost. The effect of this, no doubt, was to seal the chalk with a layer of absorbed and frozen water. During the second and prolonged frost there was the now celebrated incessant deposition of dew in the form of ice, and of snow, making a big accumulation of water on the top of the frozen layer. Then came the final thaw. With it, for the first time within living memory, a stream appeared and flowed briskly down the dene, doing a little water sculpture on its way and leaving some tiny deposits which will make good Combe rock in the future.

How rare such an occurrence is under modern conditions is shown by the fact that my house is built in the very bottom of the dene. So it gave difficulties to the stream, out of which it could find no better way than to run straight through the house from the front door to the back.

During the second great frost the young trees were so weighted with solid ice that the tops of many were bent to the ground and old trees had great boughs broken—a strange sight but one not unseen before, for a student points out to me these passages in a letter of Erasmus:

"Deinde grando, tum et pluvia, quae simul atque terram arboremve contigit protinus in glaciem concreta est. Vidisses arbores glacie vestitas adeoque pressas ut aliae summo cacumine imum solum contingerent, aliae ramis lacerae. Jurabant nobis e rusticis homines natu grandes se simile nihil unquam in vita vidisse antea."

KENNET OF THE DENE.

Lockeridge
March 1.

Points from Foregoing Letters

A RECENTLY published account by H. F. Bain describes the isolation from unsterilized roots of *Vaccinium macrocarpon* growing in America of a mycorrhizal fungus specifically distinct from the *Phoma radicis* isolated by Ternetz from sterilized roots of native Swiss species of Vaccinium in 1907. In view of this discrepancy, M. C. Rayner and I. Levisohn have investigated British material of *Vaccinium Oxycoccus*, and now record that the fungus isolated by them from sterilized roots of this species agrees in every particular with that isolated by Ternetz.

O. N. Purvis has successfully vernalized fragments of winter rye embryos consisting of the stem apex and one leaf initial only, by culturing on a suitable medium for six weeks at 1° C. The response was less than that of whole embryos to similar treatment.

The toxicity of poisons used in insecticides depends primarily on the physico-chemical relations of the toxic principle and the carrier. H. Hurst finds that feebly dissociating compounds of high dielectric constant penetrate the cuticle of insects more readily in the presence of relatively apolar substances of low dielectric constant, the main region of induced penetration being at the cuticle-hæmolymph interface.

Data obtained by G. Eloff in connexion with daily counts of offspring from Drosophila cultures in which parents were left for forty-eight hours, pointed in the case of the criss-cross generation to a high emerging frequency on the fifth day of counting, especially accentuated in the case of the males. In the case of pure yellow-white cultures of *D. melanogaster* the females also showed a strong fifth day peak. The phenomenon, which is probably associated with lowered viability, was absent in the case of wild cultures of *D. melanogaster* and *D. simulans*.

A new species of Amœba of the genus Chaos has been isolated and cultivated and is briefly described by M. Taylor and C. Hayes. *Amœba lescheri* is slightly smaller than *Amœba proteus* Y., which it resembles in many ways. The nucleus, which is discoid and situated in the peripheral endoplasm, divides amitotically. Fission of the cytoplasm can take place while the amœba floats and occurs once a day.

H. G. K. Westenbrink and D. A. van Dorp have investigated the cause of the apparent activation of the carboxylase system by free aneurin. In their opinion it is caused by the inhibitory effect of aneurin on the hydrolysis of cocarboxylase by phosphatase, present in the alkaline washed yeast.

RESEARCH ITEMS

Rostro-Carinate Stone Implement from Rhodesia

Implement-bearing talus on the lower slopes of the Gwelo Kopje, Southern Rhodesia, known for some years to students of Rhodesian prehistory as the source of a sequence of stone implements in which flake implements are associated with *coups de poing*, has now produced an undoubted rostro-carinate which is described by Neville Jones (*Trans. Rhodesia Sci. Assoc.*, 37; 1939). The implement is of special interest as it is the best example of the form as yet found in Southern Rhodesia, and its occurrence in a deposit which contains no evidence of fracture from natural causes after deposition gives added weight to the claim for the human manufacture of this type of implement. It is the only unmistakable rostro-carinate found at Gwelo. The form is characteristic in that it is fairly symmetrical and broadest at the posterior end, from which it tapers to a sharp point, which imparts to it a beak-like appearance. The ventral surface is unflaked and presents the natural weathering. Parallel with this is the small dorsal platform, originally triangular, from the apex of which the keel begins and extends to the top of the 'beak'. The sharp-edged keel is strongly curved in elevation, fairly true to the median line and is slightly sinuous in plan. It is formed by the removal of a wide flake on each side. The weight is 1 lb. 6 oz. Though there is no evidence of comparative age, it may be claimed, from analogous finds at Hope Fountain, to be a tool of early type.

Studies of American Cities and States

A study of American cities and States by methods which have proved valuable in the study of individual persons has been published by E. L. Thorndike (*Annals N.Y. Acad. Sci.*, 39, 213–298; 1939). Variations and correlations in institutions, activities and the personal qualities of the residents have been obtained for each city in the United States having a population of more than 30,000 in 1930, but excluding the cities of more than 500,000, except Milwaukee, and the three resort cities, Atlantic City, Miami and St. Petersburg. The 296 different items examined covered population and growth, value of public property, literacy, expenditure on public services, sales and prices, rents, salaries, mortality figures and vital statistics, occupational data, membership of institutions, etc. The data show very great variation in important features of life and welfare, and for each city and State composite scores have been computed which may be used as indexes, respectively, of the general goodness of life for good people in the community in question, the *per capita* income of its residents and their personal qualities of intelligence, morality and care for their families.

Growth and Feeding of Young Herring

S. M. Marshall, A. G. Nicholls and A. P. Orr have continued their studies on the growth and feeding of young herring in the Clyde (*J. Marine Biol. Assoc.*, 23, 1939). The last paper dealt with growth from spawning to metamorphosis; the present paper gives the results of an attempt to continue the work from metamorphosis up to the formation of the first winter ring. Two distinct groups were met with. The first, obtained during July 1936–May 1937, were caught inshore; the second, of which only a few catches were taken, in 1937 and 1938, were caught offshore. The second group is shown to be of the same origin as those discussed in the previous paper. Details are given of counts of vertebræ and lengths for race determination, size and growth, weight, chemical composition and food. A series of hauls made over a night showed that the herrings were most abundant inshore at dusk and dawn and contained most food during 7–11 p.m. The food was examined throughout the year and compared with the plankton hauls. Copepods, as is usually found, formed the main diet, but other organisms were at times plentiful, coinciding with their abundance in the plankton. Thus when cirripede larvæ were common in the plankton, the stomachs were full of them; this was also the case with Cyphonautes. With Calanus it was different, this copepod being frequently common in the gut and quite absent from the accompanying plankton hauls, which suggests that the herring had been feeding offshore before they were caught, although the presence of typical littoral plankton shows that they fed inshore as well. In general the results of the food investigation agree with those of other workers.

Amphibian Anatomy

Various features of the skeletal elements of the skull, hyoid apparatus and vertebral column of the Amphibia have been employed for the purpose of systematic diagnosis. In a recent paper, L. S. Ramaswami (*Proc. Ind. Acad. Sci.*, 10; 1939) has critically examined these as recorded in previous literature and in the light of his own considerable experience in five genera of anurous Amphibia. He has already published a series of detailed observations on this subject (1932–37), and the present paper serves in some respects as a summary of these. A number of criteria previously used are shown to be of no use, and the author concludes with a detailed list of the characters that can be used in the Ranidæ, Rhaophoridæ (Polypedatidæ), Microhylidæ, Bufonidæ and Pelobatidæ.

A New Species of Rose

The expedition of Captain F. Kingdon Ward to Tibet in 1924 resulted in the introduction of several rose species to European horticulture. One of these, No. 6101, was provisionally named *Rosa Sweginzowii* var. *inermis*, but Mr. B. O. Mulligan, who has examined several shrubs now in cultivation in England, considers it to be a new species, which he has named *R. Wardii* (*J. Roy. Hort. Soc.*, 65, Pt. 2; February 1940). A full diagnosis is given. The rose is attractive from a garden point of view, bearing white flowers with striking red centres.

Filterable Viruses

A useful review of the filterable viruses of animals and plants has recently been published by L. J. Davis (*Proc. Rhodesia Sci. Assoc.*, 37; September 1939). Consideration is given to modern findings under the various headings of filtration, microscopy, possible culture, pathology and host relations, chemical composition, and resistance to inhibiting agents. Perhaps the most interesting section, however, is that on the nature of viruses. The question "Are they Animal ?" is dismissed somewhat summarily, and the evidence as to their vegetable or mineral nature leads to the general conclusion that "viruses, or at least some of them, while manifesting the properties of living matter may actually occur in a form never before known to be compatible with life, a kind of non-cellular life".

Bacteriophage and Plant Lysins

THE origin of the mysterious bacteriophage, the transmissible agent which dissolves living bacteria, has never been accounted for. It was discovered by Twort and arises spontaneously in cultures of bacteria under certain conditions. D'Herelle maintains that it is a living ultra-microscopic agent, others believe that it is a chemical agent, capable of regeneration, analogous to a plant virus. In a paper communicated to the American Association for the Advancement of Science at Columbus, Ohio, in December last, Roy C. Thomas suggests a possible mode of origin. He finds that a non-specific lysin or 'dissolving' agent is found in many plants. It is inactivated by heating to 56° C. for thirty minutes, and has much the same action upon bacteria that bacteriophage has. When this lysin comes into contact with bacteria susceptible to its action, a change occurs resulting in the formation of a transmissible lytic principle similar to bacteriophage ; it is not inactivated at 60° and only partially at 65°. It is suggested that this is the origin of the bacteriophage, at least in plants. With regard to corn wilt bacteria, with which much work was done, a bacteriophage can be obtained for any strain which does not contain one, and a phage developed for a culture is highly specific for it.

Fluorescence of Diacetyl

KALLE (*Naturwiss.*, 25, 61 ; 1937) observed that when aqueous diacetyl is irradiated with violet or near ultra-violet light it exhibits a vivid green fluorescence which increases from zero to a constant saturation intensity. Almy, Fuller and Kinzer (*J. Chem. Phys.*, 8, 37 ; 1940) have shown that this delay is caused by the quenching action of dissolved oxygen which is ultimately consumed. On outgassing, the fluorescence appears immediately in its full intensity. Oxygen and carbon dioxide quench the fluorescence temporarily. They also found that diacetyl vapour exhibits fluorescence. The fluorescence spectra of both are identical with that of acetone excited by 3130 A., but, in contrast to diacetyl, the fluorescence of acetone rises gradually from zero intensity. This is explained by assuming that the fluorescing molecule in both instances is diacetyl. The fluorescence of acetone will then grow in intensity as the concentration of diacetyl in it increases. Further, acetone is excited by 3130 A., which does not affect diacetyl. This is considered due to the formation of diacetyl molecules excited by collisions of the second kind, diacetyl with excited acetone molecules, or by a three-body collision of diacetyl with two combining radicals. The fluorescence spectrum of diacetyl was found insensitive to changes in diacetyl pressure (0·1–50 mm.), temperature (10°–100°), and exciting wave-length (3650–4358 A.). The ratio of intensity of fluorescence to light absorbed is independent of the pressure, and the intensity is linearly proportional to the exciting intensity at constant pressure. The quenching of fluorescence by oxygen follows the Stern-Volmer law over the range in which the fluorescence falls to 20 per cent of the initial intensity ; at higher pressures the intensity falls more rapidly than is expected. The life-time of the fluorescing molecule is estimated as 10^{-5} sec.

Insulation Stresses in Transformers

A PAPER read by J. L. Thomas to the Institution of Electrical Engineers on February 22 discusses the stresses in the insulation of transformers, with special reference to surges and electrostatic shielding. The normal working voltage per turn on even the largest transformer is not likely to exceed about 100 volts. Hence the amount of inter-turn insulation required for normal working conditions is ample when compared with the minimum considered necessary mechanically. The established standards of high-voltage tests, which originally had an empirical origin, have resulted in major insulation proving itself generally adequate by satisfactory service records even in districts subject to severe lightning. At the present time, the principal application of 'non-resonating' shielding is in connexion with transformers for exceptionally high voltages of 220 kv. and above. The mathematical theory shows that the effect of the shielding is to reduce the space harmonics, and in particular the higher harmonics, and so to reduce the peak voltage gradients. Oscillograms are shown of a large number of tests on the effects of shielding. In all cases the shields have been shown to effect a substantial improvement. Results are given of tests on a three-phase 88 kv.–8,000 kva. transformer in oil. The large effects produced by 'chopped' impulses on inter-coil voltage transformer windings with and without shields are shown. The author shows that shielded winding makes possible an economical design in which it can be ensured that inter-cell failure under impulse conditions will not occur before major insulation breakdown.

Meteor Observations from India

MOHD. A. R. KHAN, Begumpet, Deccan, has sent an account of his observations of meteors in 1939. Altogether he recorded the paths of 1,233 meteors and these included members of some of the major showers. The maximum display of Orionids was attained on October 19, a total of eight being observed between 21h. 30m. and 22h. 30m. ; on October 17 only two were seen and on October 18 five. Two of the latter were very bright, with magnitudes – 1 and – 2·5. On November 13, 27 meteors were observed between 22h. and 23h. but only 5 of these were Leonids. On November 14, out of 13 meteors observed from 20h. 45m. to 21h. 30m., there was one Leonid, and on the following night during watches extending over 1h. 15m., out of 8 meteors there were 5 Leonids. On November 16, during a watch of 45m., a total of 30 meteors was observed, 5 of which were Leonids. On December 12, in a watch of 2h. 10m., a total of 74 meteors was seen, 15 of which were Geminids. Although most of these were faint, as is usual with this shower, there were three bright meteors, of magnitudes 1, 0, and – 3 respectively. On December 14 watch was maintained for 1h. 20m., and 10 Geminids were observed, 4 of which were fairly bright. Careful watches were kept on October 9 at different times for Giacobinids, but none was seen ; on the following night clouds rendered observations useless.

INDIAN SCIENCE CONGRESS ASSOCIATION

MADRAS MEETING

THE DECCAN TRAPS: AN EPISODE OF THE TERTIARY ERA

AT the dawn of the Tertiary era, vast outpourings of basaltic lavas covered immense regions in the north-western United States, in the old Thulean province which extended from Greenland to Scotland and Ireland, and in the Deccan. In estimating the exact geological age of these lavas, much depends on the interpretation of the fossils (chiefly plants) from interbedded sedimentary deposits. Recent work on the interbasaltic flora of the Hebrides was summarized by Sir Albert Seward in his presidential address to the British Association at Dundee in 1939, and now Prof. B. Sahni, presiding at the twenty-seventh Indian Science Congress held in Madras during January 2–8, has discussed the Inter-Trappean flora of the Deccan.

Fissure eruptions, Prof. Sahni thinks, may once have spread sheets of lava over some half million square miles, and even after continuous erosion for millions of years the Deccan Traps still cover an area of 200,000 square miles. Thickest along the west coast (six to ten thousand feet), their abrupt ending gives no measure of their extension over a tract of land that foundered into the Arabian Sea.

The flora is known mainly from sediments in the Nagpur and Chhindwara districts of the Central Provinces, occurring between some of the lowest and oldest flows in the whole series; the plant-bearing beds at Rajahmundry on the east coast are also low in the series. No Inter-Trappean beds have yet been discovered in the middle part, and the lava-flows may have issued in such rapid succession that there was no time for extensive colonization or deposition of sediments. (The plant-bearing beds of western Scotland are also found between some of the basal flows.) At Bombay Island the upper members of the Deccan Traps include sedimentary beds yielding a pigmy frog and other organic remains, but no plants have yet been recorded. The highest Traps are in places covered by marine beds of known Eocene age, which fixes an upper limit for the age of the series.

The view that the Traps were poured out during the Cretaceous is not supported by the fossils. One of the most conclusive single pieces of evidence is the occurrence of fruits belonging to the brackish-water stemless palm Nipa, a plant characteristic of Eocene beds at many points near the shores of the former Tethys Sea, for example, in the London and Paris basins, in Poland, southern Russia and Egypt. The palms, known from numerous fruits as well as from abundant petrified wood, dominated the Inter-Trappean flora; although this family arose in the Cretaceous period, it did not become prominent until after the Tertiary era had begun. The abundant charophyte fruits support an early Tertiary age, while the water-ferns, unknown from pre-Tertiary rocks, are represented by a beautifully preserved Azolla.

Numerous other elements in the flora are of botanical rather than geological importance; they include fungi belonging to the Perisporiaceæ and Sordariaceæ, many types of spores, and various dicotyledonous fruits.

GALACTIC DYNAMICS

For his presidential address in the Section of Mathematics, Prof. A. C. Banerji chose as his subject "The Development of Galactic Dynamics and Some Allied Problems". Under this heading was considered a wide selection of the mathematical researches that have been made into the effects of rotation on gravitating masses.

The survey began with the classical researches concerning the stability of spheroids and ellipsoids of uniform density, and went on to a discussion of the pear-shaped figure, while the later work of Jeans on the analogous behaviour when the mass is compressible was also touched upon. The possibility of extending the treatment to the case of a fluid under more general physical conditions led to the recent investigations by Milne, Bhatnagar and others on the distortions that a fairly small rotation would cause in polytrophic distributions, and in particular Chandrasekhar's results for double stars. The work by Eddington in which any spherical distribution can be discussed by means of a variable polytropic index was considered next and reference was made to the special feature of this method, that many properties are intermediate between the corresponding properties of the two spheres whose polytropic indexes are the extreme values of the variable polytropic index.

Turning to the problem of rotating nebulæ of galactic dimensions, the discussion was commenced by describing Hubble's classification of the various observed types. Before proceeding to the problem presented by the spiral arms of nebulæ, the difficulties found by Jeans concerning the impossibility of the formation of stars in an equilibrium configuration of a nebula were brought forward. As for the theories of the spiral forms of the arms, Jeans's point-mass model was considered first to demonstrate the difficulty that the existence of stars is incompatible with the necessary gaseous structure of the nebulæ. The results obtained by E. W. Brown that spiral arms could persist for long periods only under very artificial systems of forces were quoted next, and in the same category were taken the more speculative suggestions of Vogt and Lambrecht postulating cosmical repulsion in the galaxies. Proceeding to our own galaxy, it was suggested that the differential rotation may be an indication of instability in the outer regions.

Arising out of the question of the formation of spiral arms, Prof. Banerji said that it is first necessary to decide whether in Newton's second law the impressed force is proportional to the mass times the acceleration *or* to the rate of change of momentum, and various opinions on this point were cited. The existence of interstellar matter and its possible dynamical effects completed the account given of galactic problems.

In conclusion, Prof. Banerji referred to the recent advances in the theory of the origin of the solar system. It was explained how the former difficulties relating to angular momentum had been resolved by Lyttleton, starting with the hypothesis that the planets were formed from a companion star to the sun during an encounter with an intruding star.

The effects of tidal friction in bringing about some of the detailed features of the solar system were briefly discussed, as, for example, the suggestion that the slow rotation of Venus can be explained by supposing that Mercury was formerly a satellite of this planet, and that the retrograde satellite of Neptune arose as a result of an encounter between two direct satellites, of which one escaped as an independent small planet (Pluto), and the other was diverted into a retrograde orbit.

MAGNETIC STUDIES OF AROMATIC MOLECULES

Prof. K. S. Krishnan delivered the presidential address to the Section of Physics, taking as his subject "The Diamagnetism of the Mobile Electrons in Aromatic Molecules".

Prof. Krishnan pointed out that our knowledge of aromatic molecules, particularly benzene, has been extended very considerably during the last few years by the quantum-mechanical treatment of the linkages and valency electrons and by the experimental determination of the symmetry and normal modes of vibration by means of infra-red and Raman spectra. It is now known that in benzene one electron of each carbon atom is mobile and can move from carbon to carbon, conferring on the molecule magnetic properties somewhat similar to those of free electrons in metals.

Outlines were given of the theories of paramagnetism of an electron gas and of diamagnetism of a free-electron gas; and the experimental data on graphite were reviewed with special reference to the temperature variation of magnetic anisotropy. These data verify Landau's view that quantization of the motion of free electrons in the magnetic field leads to a balancing between the diamagnetic and paramagnetic contributions, and that the temperature-independent diamagnetism of the free-electron gas is one third of its paramagnetism.

Mobile electrons in aromatic molecules are free to move anywhere in the ring; this is the same as postulating resonance between canonical structures, five of which are required for benzene, whilst for naphthalene 42 and for anthracene (or phenanthrene) 429 are necessary. Mobile electrons in aromatic molecules give rise to abnormal diamagnetism in the direction perpendicular to the plane of the ring and, consequently, to large diamagnetic anisotropies. For single crystals of such magnetically anisotropic molecules, if the magnetic constants are known, orientations of the molecules in the crystal lattice can be deduced, or, conversely, if molecular orientations are known from X-ray data, the principal magnetic constants of the molecules can be calculated. This calculation supports the theory when applied to sixteen aromatic molecules, and the contribution of mobile electrons is approximately proportional to the number of benzene rings in the molecule. These mobile electrons also give rise to optical effects, fluorescence and absorption, in both of which it is the component parallel to the molecular plane which is active. Not only are mobile electrons associated with benzene rings, but also with other conjugated ring structures, for example, cyanuric trichloride and phthalocyanine.

The address concluded with a brief consideration of theoretical calculations of the magnitude of diamagnetic anisotropies.

ROLE OF CHEMISTRY IN FORESTRY

Dr. S. Krishna, presiding over the Section of Chemistry, covered a wide range of topics in his address upon the role of chemistry in forestry. His topic is very suitable to current conditions, as it directs attention to the many ways in which Indian sources of supply, of drugs, dyes, tanning material and the raw material for many industries might be drawn upon, with increased income for the country and a diminished demand for imports. The work of the chemist was reviewed in connexion with production, conservation and utilization, but perhaps the main emphasis was placed upon the latter.

Very interesting Indian examples were cited of differences in chemical constitution and of economic importance, which had remained unrecognized by the systematist. In the Kurram valley (North-West Frontier Province) two varieties of *Artemisia maritima* grow side by side, one of which yields nearly 2 per cent of santonin but the other has none; only later was it noted that the young plants of the valuable forms had reddish stems, while the others were green at this stage. Four varieties of *Eucalyptus dives* exist, morphologically indistinguishable, but yielding oils with piperitone content ranging from 5 to 50 per cent. In connexion with seasoning, problems of timber impregnation were discussed, and attention was also directed to the recent Russian experiments using ultra-short waves.

Considerable attention was given to the possibility of increasing forest revenue by greater utilization of minor products. Baluchistan forests, run at a deficit for more than thirty years, have recently become solvent on the sale of Ephedra. Although many minor products would not repay harvesting on a large scale, they may have possibilities if organized on the lines of 'cottage industries'. Amongst minor 'forest' products, grasses and bamboos have supplied most revenue, particularly for the production of the better grades of paper. Another minor product available to prevent present imports is turpentine, now obtained from the oleoresin of *Pinus longifolia*. This is not so rich in pinene content as the turpentine from other species of pines such as *P. excelsa*; when such sources are tapped, they would be available for conversion into camphor, at present wholly imported.

Dr. Krishna advocated the formation of an association to stimulate the cultivation and utilization of medicinal plants in India, in order to promote the utilization of India's very valuable drugs, sources of many of which are found in India's forests.

THE UPPER CRETACEOUS AND LOWER EOCENE

Prof. L. Rama Rao, in his presidential address to the Section of Geology, took as his subject "Recent Advances in our Knowledge of the Upper Cretaceous and Lower Eocene Beds of India, with special reference to the Cretaceous-Eocene Boundary".

During the past few years several geologists, working in various parts of India, have made material contributions to our knowledge of the stratigraphy and palæontology of the uppermost Cretaceous and Lower Eocene rocks of this region. Much new light has thus been thrown upon the position and nature of the Cretaceous-Eocene boundary and upon questions of palæogeography.

The Ranikot beds, long ago recognized as the basal division of the Eocene in Sind, have been shown to be of pre-Ypresian age. They are now known to be much more widely distributed than was formerly supposed, occurring also in the North-West Frontier Province, the Salt Range, Kashmir, Tibet, Burma, and western Iran. In the Samana Range (North-West Frontier Province) the Hangu Shale, with its rich fauna, seems to constitute the lowest fossiliferous horizon of this formation anywhere known; it is separated from Upper Cretaceous deposits by a conformable series of beds which, however, have yielded no fossils. A similar transition from the Cretaceous to the Eocene seems also to exist in Burma and possibly in Tibet.

In the Peninsular area interesting discoveries of fossils have recently been made in beds intercalated in and underlying the Deccan Trap; their study has led to the conclusion that the Trap belongs to the Lower Eocene rather than to the Cretaceous, as formerly supposed. The well-known Infra-Trappean bed of Rajahmundry would appear to lie almost upon the border-line between the Cretaceous and the Eocene. Prof. Rama Rao's own researches have led to the important new discovery of Lower Eocene beds overlying the Cretaceous in the Pondicherry district. Especial reference was made to the study of the fossil algæ of many of the rocks under discussion, as this work is proving of great help in their correlation.

In discussing, next, the geography of early Eocene times, Prof. Rama Rao visualizes, in the west, an arm of the ancestral Indian Ocean stretching northward so as to cover Sind, Baluchistan, parts of the Punjab, the North-West Frontier Province, and Kashmir; and dividing, in the north, into two branches, which extended respectively to Iran and Tibet. A second arm of this sea, situated to the east of India, extended northward into parts of Assam and Burma. Reference was made to the divergent views of various authorities as to whether there was direct communication with the Mediterranean Sea of that period.

In his concluding remarks, Prof. Rama Rao pointed out that the great geographical changes which heralded the incoming of Tertiary times must everywhere have affected the balance of marine life; hence a normally evolving succession of forms may not have persisted even in those parts of the sea where sedimentation was uninterrupted.

GEOGRAPHY IN NATIONAL PLANNING

The Section of Geography and Geodesy was formed on the occasion of the Jubilee meeting at Calcutta in January 1938, when its sessions were attended by a strong delegation from Britain. The president this year of the Section was Dr. S. P. Chatterjee, and in his presidential address he directed attention to the part which should be played by geographical studies in national planning.

A stock-taking of resources on a provincial basis is an essential pre-requisite of any work of national reconstruction, and that there is no country in the world where there is a greater need of a detailed land utilization survey than India. The assertions that in Bengal, which is selected for study as Dr. Chatterjee's native province, the land is deteriorating, soils losing fertility, marshes and lakes increasing in area at the cost of good arable lands, and river-borne sediment failing to build up the land, all require substantiation. The official statistics, skilfully shown in cartographic form, show that only one third of British India (contrasted with nearly half of 'Indian' India) is actually cropped. In Bengal, which in places supports a *rural* population, albeit in a condition very near the starvation level, of a thousand persons per square mile, no less than one quarter of the whole province is classed as fallow and cultivable waste, whilst less than half is actually cropped.

Dr. Chatterjee has clearly appreciated his training both in the French school and in Britain, and has attacked the problem on a regional basis. He gives the preliminary results of a survey carried out in the past two years and suggests a division of Bengal into ten regions. As frequently happens, the local cultivators know and appreciate small differences in soil and the local names (mainly based on texture) have been used to divide the new alluvium into ten types the distribution of which is shown on an instructive map.

As Chatterjee says, "since national planning means a conscious effort of man to change his environment in the best national interest, it is rational to be equipped with a thorough and accurate knowledge of the type, historic growth and present distribution of the various factors that go to form our cultural landscape, which is the subject matter of geography", and on this basis he appeals for an All-India organization for conducting a geographical survey.

(To be continued)

AIR CIRCULATION OVER INDIA

A MEMOIR of the India Meteorological Department (26, Part 10) by K. R. Ramanathan and K. P. Ramakrishnan, entitled "The General Circulation of the Atmosphere over India and its Neighbourhood", is probably the most complete account that has yet appeared of the average winds and temperatures in the upper atmosphere over India in each month of the year.

The observations of upper wind made with the aid of pilot balloons at observatories, and those of cloud movement, together with the measurements of temperature aloft by sounding balloon made at Agra, Poona and Hyderabad, form the basis of the discussion. Mean isotherms for various levels up to 6 km. were obtained partly from the changes of wind with height, from which the mean magnitudes and directions of the temperature gradients were calculated, and partly from the mean temperatures at the different heights for the three upper air observatories, supplemented in some cases by temperatures measured at Peshawur or Quetta. Although in theory it is sufficient, having obtained a chart of temperature gradient, to have the vertical distribution of temperature at only a single station in order to be able to draw the absolute values of the isotherms, in practice, the computations being only approximate at every stage, the accuracy of the final picture was increased by having means of temperature at several places.

The results are set out in 74 plates, the mean air movement being taken up to 8 km. The main features of the upper wind and temperature distribution in the different months are discussed and then summarized (pp. 192–207). The most striking feature of the circulation is the regular seasonable movement of the upper wind system, which in the summer half of the year is from south-east to north-west and back, and in the remainder of the year is mainly from north to south and back. The smallness of the month to month movement from December to April or May is taken to signify that cooling and heating of the ground over India by radiation does not greatly modify the circulation, the big changes being caused by the northward penetration and the subsequent retreat of moist air from the southern hemisphere with its attendant rainfall.

Other striking features brought out by this study are the modifying influence of the Himalayas up to a height of 6 km., and the fact that regions of heavy rainfall become regions of high temperature and divergence of air movement above 6 km. The mean winds derived from cloud movement have a much larger northward component than those derived from pilot balloons, which last require absence of cloud so that the balloon can be followed. A true picture of average conditions cannot therefore be obtained from either method alone.

ECONOMICS OF WAR-TIME EXPORT TRADE

A VALUABLE broadsheet "Exports in War" issued by Political and Economic Planning (P E P) reviews the question in relation to the economics of war and the principles upon which the export policy of Great Britain should be based. The object of exporting at all is to save man-hours, and in war-time to avoid mortgaging the future by the sale of overseas securities. Because of our limited ability to pay for imports in exports or foreign securities and our restricted capacity to ship them over, there must be discrimination between different types of demand for imports, giving priority to those which are most urgent from the point of view of winning the war.

The broadsheet stresses the basic importance of applied intelligence in exports; in war, it is particularly important to concentrate on those goods the selling price of which includes least matter and most mind, and the seller's market which is being created by the War should be utilized to grade up export industries instead of clinging to older and less profitable lines. Similarly, every opportunity missed of improving productive efficiency is a drag on the national effort. If new layers of demand are continually tapped and labour and capital progressively transferred to more and more advanced processes or products, the shrinkage of formerly important export industries can be faced without dismay. Moreover, if we make the inter-allied economic arrangements between France and Great Britain work effectively, we shall not only have won the war but made also the greatest possible contribution towards winning the peace.

These agreements between France and Great Britain are outstanding among the actual War-time economic measures. With the joint committees on economic co-operation covering the supply and purchase of munitions, food and raw materials, shipping policy and economic warfare, they should lead to one economic policy for the two countries. This is specially true of exports. The three major elements in any export policy are the export potential, the available markets and the foreign trade policies. The nature of the export potential is the most important in a sellers' market, but exports cannot be left to take care of themselves after the needs of the armed forces and of the civilian population have been met, but must be recognized as a priority of the first importance. Among the opportunities for expansion of our exports at present, the broadsheet stresses those in machinery to complete unfinished German contracts, and those in cotton textiles, locomotives and coal.

The effect of the contraband control on export policy must next be recognized. The purpose of such control is to impede the supply of vital commodities to the enemy. This has now been extended to exports, so that Germany's direct overseas trade should soon be virtually destroyed. Particularly in Latin America, the control has created new markets for Great Britain, and for this our bargaining position is in general strong.

The second aspect of economic warfare consists in the extension of the effects of the blockade to the Continent, so as to cripple Germany's trade with those neutrals with whom contact can still be maintained. The object of promoting British exports to European countries is to turn the tide of trade heavily against Germany by raising the prices of neutral products. This involves a careful study of the strategy of economic warfare, if Germany is to be prevented from importing from neighbouring countries. Strategic purchases, for example, of Rumanian oil involve British exports to pay for them. Sound export policies, moreover, can only be framed after the fullest information about markets and resources has been obtained, and such policy covers every aspect of exporting from production to marketing, including the use of bilateral or multilateral methods of approach to markets, import or export subsidies.

A large-scale purchasing programme makes a survey of the export potential more urgent, and the existence of these Anglo-French programmes is an important factor for world producers. Overseas Governments will require to know that resources are available to supply the necessary goods if they are to continue to sell to Britain, and also that exports have priority over alternative demands. The importance of paying sufficient attention to the needs of the non-self-governing colonies is stressed in the broadsheet, which adds one further plea to the many already advanced for a co-ordinator of trade policy with sufficient political status, including access to the Cabinet, to secure the full and coherent use of Great Britain's immense resources for acting as a centre of world economic expansion.

PRODUCER GAS FOR MOTOR VEHICLES

THE recently published "Report of the Committee on the Emergency Conversion of Motor Vehicles to Producer Gas" (London : H.M. Stationery Office, 1940. 9*d*. net) conveys conclusions only. The Committee, set up by the Mines Department in May 1937, carried out extensive experimental work, including bench tests and road tests under normal operation and under scientifically controlled conditions, from which it can be inferred that a considerable body of quantitative information was derived. The data, however, have not been published; presumably it was not desirable to give details of the work at the present time.

Road trials with commercial producers showed that, subject to certain inherent limitations, producer gas is a satisfactory fuel for transport vehicles. The Committee was impressed by the difficulties encountered and the special conditions attending such an emergency as was envisaged, and therefore undertook the design of a simple producer which would be suitable for the conversion of existing vehicles, capable of rapid production at low cost and required only such metals, plant and labour as were likely to be available in war-time.

Although on the Continent considerable numbers of vehicles have been operated by producer gas, the small amount of progress made in Great Britain is put down to increased capital maintenance and servicing costs, reduction in power output with the consequent upsetting of operating schedules, reduced pay load and the difficulty of obtaining suitable fuel. The artificial disadvantages due to such vehicles being placed in higher tax and lower speed-limit categories are probably more potent considerations. It is stated that the vehicles operated by the Committee have covered a distance of more than 170,000 miles, but no information is adduced regarding these trials. Nor are any figures given of the results obtained in Continental practice, although several members of the Committee had already studied the use of producer gas vehicles on the Continent, and close watch was kept on developments taking place abroad.

The design, which the Committee states is not suggested as necessarily representing finality, appears to be suitable for vehicles up to 6 tons gross weight of 3–4 litres engine capacity. Grave difficulties in operation were found to follow relatively minor constructional defects, and failure to adhere strictly to the dimensions laid down has frequently led to trouble. The design as outlined appears to have the merit of simplicity from the point of view of manufacture and lends itself to mass production. It is suitable for use with low-volatile anthracite and certain low-temperature cokes, and may be mounted on the vehicle itself or on a trailer as thought best in each individual case. We are informed that full details regarding the plant and its working can be obtained from the Director, Fuel Research Station, London, S.E.10.

There are among the conclusions reached by the Committee several valuable items of information such as the availability of different classes of suitable fuel, effective methods of gas filtration and the classes of service for which gas producer vehicles can be most economically used.

EXPLOSIVE ACTIVITIES OF A JAPANESE VOLCANO

THE volcano Kusatu-Sirane suddenly became active with a remarkable explosion on November 27, 1937, and from that time until October 1938 it was studied in great detail by T. Minakami (*Bull. Earthquake Res. Inst.*, Tokyo Imp. Univ., 17, Part 3, September 1939, pp. 590–623). The volcano was very active during December 1937, and January and February 1938. It was more calm from April until August 1938, but became active again from the latter part of September. A rather violent explosion occurred on October 5, 1938, and after that date large quantities of gas were ejected, while ash was scattered near the *Y* crater. At the same time, volcanic pulsations and volcanic micro-earthquakes occurred and these were still continuing in February 1939.

So far as situation on the earth's surface is concerned, the active fissure differed from the fissure of previous activity of October 1932. The hypocentres of the micro-earthquakes were found to be at a depth of 1·7 km. According to geothermic measurements, the region of high temperature was restricted to the narrow zone along the active fissure. From observations of the water-level of the hot spring pond in the crater, it was concluded that the quantity of water that filtered through the fissure at the bottom of the pond amounted approximately to 750 tons a day. The gas ejected from the crater was mostly aqueous vapour, though on several days during May and October 1938 large quantities of evaporated sulphur were emitted with the steam. Boring showed that the floor of the *Y* crater consisted of alternate layers of precipitated sulphur, volcanic detritus and ash.

The presence of the sulphur gave the estimate of 444° C. for the temperature of the vapour, though often it was below this temperature. The quantity of seeping water would affect this, as would the supply of heat from the subterranean origin. Judging from the distribution of volcanic detritus, the pressure of gas at the time of the principal explosions under discussion was almost 150 atmospheres, which is slightly less than that of the explosion of October 1932 as calculated by T. Matuzawa.

H. Tsuya suggests that these explosions were phenomena near the earth's surface resembling those of a geyser.

SEVENTY YEARS AGO

Nature, vol. 1, March 24, 1870

The Transits of Venus in 1874 and 1882

"A Parliamentary paper issued at the close of last session gives some information on what is intended to be done in the matter of the great approaching astronomical events of 1874 and 1882. . . . For the proper observation of this event [the transit of 1874] the Astronomer Royal informs us that it will be necessary, after making allowance for all the aid that may be expected from foreign and colonial observatories, to organise expeditions to the following five stations :—(1) Oahu (Sandwich Islands), (2) Kerguelen's Island, (3) Rodriguez, (4) Auckland (New Zealand), (5) Alexandria. At the first three of these stations . . . it will be necessary to make preparatory observations for twelve months, in order to ascertain the absolute longitudes of these places, which are not exactly known. . . .

"But what I wish to call attention to at the present moment is the valuable opportunity thus afforded for still further augmenting the importance of this event to the progress of science generally, by converting these proposed astronomical expeditions into expeditions for general scientific observation. . . . The additional expense of attaching two or three qualified Natural History observers (or at any rate collectors) to these three expeditions could not be very great. The numerous American and Russian exploring expeditions are invariably accompanied by zoological and botanical collectors, nor is the money required to publish the results obtained by them grudged by the Governments of these countries. Even poverty-stricken Austria did not send the *Novara* round the world without a competent corps of naturalists. . . . Far from lagging behind, wealthy England ought to take the lead in such cases. . . .
P. L. S."

Conductivity of Copper

"Sir William Thomson [Lord Kelvin], having had his attention directed to the very great differences that exist in the conducting quality of copper wire professing to be of the 'highest conductivity', had a large number of specimens carefully tested and the following are some of the results obtained—the quality is indicated by the resistance of a metre length weighing one gramme. The best specimen was one supplied by M. Bréguet, Paris, of which the resistance was ·153 of an ohm per metre weighing one gramme. Specimens from English manufacturers varied as follows :—·165, ·169, ·171, ·178, ·206, ·213, ·221. Seven specimens labelled 'highest conductivity', stood as follows :—·156, ·182, ·201, ·205, ·223, and ·258. As it is to the interest of all scientific men that the copper wire used in electrical instruments shall be of the best quality, there should be general co-operation to discourage as much as possible the use of inferior copper. Variations in conductivity like those in the samples of copper mentioned above would produce instruments varying to the extent of 40 per cent."

Miss Garrett has been admitted as a member of the medical staff of the East London Hospital for Children, and was appointed one of the physicians on Wednesday last. This is the first hospital in Great Britain which has recognized in this manner the female medical movement.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned :

Second Assistant Bacteriologist and Pathologist—The Clerk of the County Council, County Buildings, Stafford (March 28).

Teacher of General Engineering subjects, including Engineering Science, Drawing and Mathematics, etc.—The Clerk to the Governors, South-East Essex Technical College and School of Art, Longbridge Road, Dagenham (March 29).

Temporary Engineering Assistant in the Waterworks Department of the Halifax Corporation—Mr. J. Noel Wood, Waterworks Engineer, Gibbet Hill, Halifax (March 30).

Lecturer in Veterinary Physiology and Biochemistry at the Veterinary College, Dublin—The Secretary, Civil Service Commission, 45 Upper O'Connell Street, Dublin (April 2).

Graduate Lecturer to teach Mechanical Engineering subjects in the Plymouth and Devonport Technical College—The Education Office, Cobourg Street, Plymouth (April 6).

Lecturer in the Mining Department of the Doncaster Technical College—The Acting Chief Education Officer, Education Offices, Doncaster (April 10).

Professor of Zoology—The Registrar, University College of Wales, Aberystwyth (April 15).

Teacher of Engineering subjects—The Principal, Technical Institute, Ladywell, Dover.

Laboratory Superintendent of the Government of Nigeria Medical Department—The Crown Agents for the Colonies, 4 Millbank, S.W.1 (quoting M/9173).

Demonstrator in Physics—The Dean, Guy's Hospital Medical School Office, Sherwood Park, Tunbridge Wells.

Technical Assistant (Male) to the Adviser in Economics to the West Midland Province—The Principal, Harper Adams Agricultural College, Newport, Shropshire.

WAR-TIME FOOD POLICY

THE publication of "Feeding the People in War-Time" by Sir John Orr and Mr. David Lubbock has served to direct public attention to a subject of the utmost importance in our war effort, namely the need for a sound and consistent policy in regard to food.*

In Great Britain the public has always been interested in food questions. The British Press devoted as much space to reviews and commentaries on the final report of the League of Nations Committee on Nutrition as did all the rest of the world's newspapers. Now rationing has given every individual a personal interest in food supplies; certainly Mr. Morrison will not complain that the country is indifferent to the doings of the Ministry of Food.

Nevertheless, the peace-time structure of the British Government machine was singularly ill-adapted to the evolution of food policies. Food supplies were not within the control of any single Minister, nor were they the principal concern of any Department of State. The Ministry of Health had a food department mainly concerned to safeguard the public from adulteration or from the cumulative effects of small quantities of preservatives. The General Department of the Board of Trade was concerned with food but, at least in recent years, mainly from the angle of the administration of import quota schemes. The Department of Scientific and Industrial Research includes the development of scientific knowledge regarding food preservation among its activities. The Ministry of Agriculture, although mainly concerned with the production of food, had no responsibilities towards the British consumer. There was thus no Ministry which could consider the food problem, either to secure adequate levels of nutrition in peace or to prepare the nation for war. When the series of political crises gave warning of the imminence of war, a Food (Defence Plans) Department was established under the Board of Trade, and this body was the nucleus from which the present Ministry of Food has been developed.

Having regard to this prior history, it was not surprising that the Food (Defence Plans) Department should not have been able to make more adequate preparations for food supplies before the War broke out. It is true that the case for obtaining large stocks of wheat, sugar and other easily stored products was urged by Sir Arthur Salter in the House of Commons and by other authorities in the Press, but it is by no means easy for a hastily constituted department to overcome the resistance of the Government machine to new proposals. As a result, Great Britain entered the War without substantial stocks of cereals, sugar and feeding stuffs, although it is understood that large supplies of edible oils and oil-seeds were obtained.

In considering the food policy during war, it is as well to compare the position of Great Britain with that of Germany. Under peace conditions, Germany produced 80–85 per cent of her total food requirements, while the contribution of British agriculture to United Kingdom requirements amounted to between 30 and 33 per cent when measured on a calorie basis. Such information as is available suggests that the German authorities have realized the importance of the protective foods, and hence, although there has been a falling off in the general standard of living of the German people, milk and vegetables have been abundant and cheap. Although Great Britain is far more dependent upon imports than Germany, the former is far less susceptible to blockade. Even if enemy action becomes more serious than it has yet been, we shall be able to rely on large sea-borne supplies reaching at least our western ports. Nevertheless, it is of the utmost importance that British agriculture should be in a position to make a maximum contribution to our requirements. This is equally important from the point of view of shipping and as a relief to the financial drain which must inevitably occur when a country mobilizes all its resources for war and must obtain large supplies of armaments, munitions and raw materials from abroad.

---

* "Feeding the People in War-Time". By Sir John Orr and David Lubbock. Pp. vii+88. (London : Macmillan and Co., Ltd., 1940.) 1*s.* 6*d.* net.
The main argument was published in an article by Sir John Orr in NATURE of March 9, p. 374.

These points have been brought out by Sir John Orr and Mr. Lubbock, but they have laid special emphasis upon another most important factor. For many months before the actual outbreak of war, indeed since the Munich Agreement, Germany has been conducting a 'war of nerves.' This war may well prove to be a contest in endurance between the English and French peoples on one hand, and the German people on the other. In such a contest it is clearly essential to pay special regard to the morale of the poorest sections of the population. Since the conclusion of the War of 1914–18, the newer knowledge of nutrition has thrown a flood of light upon the influence of food, not only on bodily health but also on the psychological reactions of the people. During 1914–18, Governments and General Staffs had little opportunity of knowing anything about such factors as the depressing effect of the lack of vitamin B_1 upon the combative spirit of armies, or the effect of shortages of the fat-soluble vitamins upon the physical, and hence upon the psychological, condition of nations. It should now be clearly realized that the staying power of a nation depends not only upon sufficient energy foods but also upon adequate supplies of minerals and vitamins.

Few will be prepared to dispute Sir John Orr's contention that, owing to the relatively high cost of the protective foods, about a third of the population of Great Britain suffer from some degree of malnutrition. This fact was established in "Food, Health and Income" and is confirmed by more recent dietary surveys. This being the case, it is not possible to disagree with Sir John's further contention that, in order to ensure the solidity of our national effort, not only must the national dietary be maintained on a satisfactory basis, but also steps must be taken actually to improve the diet of the poorest third of the population. To achieve this end Sir John Orr and Mr. Lubbock propose to adopt for food the more general proposals for an 'iron ration' suggested by Prof. J. R. Hicks and commended by Mr. J. M. Keynes. They propose that adequate supplies of a limited number of foodstuffs, selected on grounds of health and availability, should be sold at prices which would ensure that the poorest 10 per cent of the community, who may not have more than 4*s*. 6*d*. a head to spend upon food, should be enabled to purchase their full requirements of these foodstuffs at a price of not more than 3*s*. a head a week ; thus leaving 1*s*. 6*d*. a head to spend according to their tastes on other foods. It is tentatively suggested that the following foods should be selected : milk, potatoes, oatmeal, vegetables, bread, sugar and either butter or vitaminized margarine. It is maintained that, provided everyone could obtain full supplies of these seven foods, there would be no shortage of vitamins, and calcium requirements would be fully met, as well as those for other minerals. Of these foods four, namely milk, potatoes, oatmeal and vegetables, could be wholly produced in Great Britain. There is no suggestion that imports should be limited to wheat, sugar and fats, but rather that these three essentials, together with perhaps cheese and dried fruits, should be given priority on shipping space so that stocks could be built up in the country.

It is of vital importance that the policies of the British Government in regard to food and to agriculture should be so closely correlated as to be, in effect, complementary parts of the same policy. It can scarcely be claimed that this is the case to-day. Apart from the general ploughing-up policy, no clear indication of the part which British agriculture should play in the War has been given by responsible Ministers. On the other hand, the present guaranteed prices are likely to result in an enormous increase in the growing of oats, a substantial increase in wheat, and the maintenance or even increase in the fattening of cattle and sheep.

A simple method of ensuring the fullest possible production of milk, potatoes and vegetables is proposed. Farmers would be offered guaranteed markets at attractive prices for these products, not only for the War, but also for at least a three-year period after the War. This method would secure the aims sought, provided steps are simultaneously taken to discourage, by less attractive prices, an undue concentration upon cereal production or the feeding of imported concentrates to fatten cattle and sheep.

Vegetables, other than potatoes, constitute a special problem. Allotments will increase supplies, but not nearly to a sufficiently large extent. It is also necessary to stimulate farm production and to ensure that the vegetables are made available for retail sale at low prices. If, to give effect to this latter purpose, vegetable marketing is placed upon a more satisfactory basis, we shall have achieved in war something which has defeated us in peace.

It is not to be expected that the proposed food policy will obtain the support of all authorities, or that it will not encounter the opposition of special interests. The co-ordination of agricultural and import policies is, however, one of the most necessary of war measures, and the proposals under discussion do provide a logical basis for such a policy. It is also important to realize that the orientation of British agriculture towards milk and vegetable production has been advocated in the Astor-Rowntree report and by many other authorities. This war-time policy might, therefore, be expected to need little modification to adapt it to the conditions of peace.

PURE EXPERIMENT

Experimentelle Cytologie

Von Hans H. Pfeiffer. (New Series of Plant Science Books, Vol. 4.) Pp. xii+244. (Leiden: Chronica Botanica Co.; London: William Dawson and Sons, Ltd., 1940). 7 guilders; 18*s*.

EXPERIMENTAL cytology is both more and less than its name seems to say. To understand why, we have to look into its antecedents. It springs largely from the conflict of fifty years ago between vitalism and mechanism. It derives from the tradition born of this conflict, that the individual processes in the cell were physicochemical processes and that the cell as a whole, and even the organism as a whole, were to be completely understood by measuring and putting together these individual processes. Inspired by this doctrine, and inspired as well by the missionary zeal of Jacques Loeb, experiments were carried out which achieved their first purpose. They drove vitalism into the philosophical backwoods of biology, and in performing this apparently negative service they laid what should have been the foundations of a new science.

But unfortunately, while this was going on, a cleavage arose in experimental method. It was discovered that experiments of a rigorous kind could be carried out with the cell using biological as well as physical variables. Measurements could be made not only with variations in physical agents, such as temperature and *p*H, using physical properties, such as refractive index, surface tension, permeability, osmotic pressure, viscosity, specific heat and so on. They could also be made with variations in biological agents, such as genes, chromosomes, and nuclei, affecting biological properties measured in different ways and with different degrees of refinement. The methods used with these two kinds of approach became more divergent as the apparatus and the technique of each method became more elaborate. It is therefore important to see after this lapse of time whether the divergence depends on a necessary cleavage of purpose or whether it is perhaps artificial and spurious.

The "experimental" cytology which Dr. Pfeiffer describes is of the physical kind, and we have to admit that it still has the character of transplanted physics. After a lifetime of transplantation it does not appear to have developed an organic or integrated quality. It amounts to little more than a catalogue of measurements of the properties already referred to, a catalogue so disconnected that its several sections can be read in any order without loss of coherence. The method and the apparatus, it seems, are the connecting links, and not the results obtained by them. Where we might hope for analysis we find only description. The wheel has come full turn. Experiment having lost its purpose has lost its design. It has ceased to be an instrument of planned discovery and has become merely a repetitive occupation.

This decay in physical cytology was noticeable to some observers ten years ago. To-day in Dr. Pfeiffer's book it has become obvious by contrast with the biological method. The physical approach has been to the cytoplasm. It has yielded, as we may say, a series of anecdotes. The biological approach has been to the nucleus. It has yielded a connected story. The reason is perhaps a surprising one. The nucleus owes it predominance over the cytoplasm in growth and heredity not so much to a greater complexity of its components as to the permanence and precision of their structure. This precision has been shown by tests of X-ray mutation, ultra-violet spectroscopy and micro-chemistry combined with the general body of comparative and analytical cell and genetic studies (all of these left out of consideration by Dr. Pfeiffer). This in turn has meant that physical, chemical and biological methods of attack on the nucleus could be used, and used in combination, in a way that has not been possible in dealing with the undefinable cytoplasm; and in this attack, strangely enough, no one is any longer concerned to know whether the analytical operation is experimental or whatever the alternative may be.

Dr. Pfeiffer's book does a service in making the lesson of this contrast clear. The cell is a physicochemical mechanism, but it is a highly integrated mechanism. This integration can never be understood by means of experiments using variables of one kind alone, external or internal. We have to know it at each level of integration before we can fit the different levels together. Wherever we see a chance of such fitting together we must seize it.

> "*Dich im Unendlichen zu finden*
> *Musst unterscheiden und dann verbinden.*"

For this task, planning and co-ordination are necessary at every step. The co-ordination requires that we shall break down the segregation of plants from animals, of chemistry from genetics, and of experiments from less refined demonstrations. The planning requires that we shall not merely ask the right questions but ask them in the right order, without regard to departmental exclusiveness or (may we say it?) technical snobbery. C. D. DARLINGTON.

THE HISTORY OF GEOLOGY

(1) The Birth and Development of the Geological Sciences

By Dr. Frank Dawson Adams. Pp. v+506+14 plates. (London: Baillière, Tindall and Cox, 1939.) 22*s*. 6*d*.

(2) A Source Book in Geology

By Prof. Kirtley F. Mather and Dr. Shirley L. Mason. (Source Books in the History of the Sciences Series.) Pp. xxii+702. (New York and London: McGraw-Hill Book Co., Inc., 1939.) 30*s*.

IT is now more than thirty years since a comprehensive treatise on the history of geology has appeared in the English language. For long Sir Archibald Geikie's admirable "Founders of Geology" and von Zittel's "History of Geology and Palæontology" have been the standard and, in fact, almost the only works exclusively devoted to this subject available for students. Since they were written, fresh studies in the history of geology have appeared from time to time, both in Europe and the United States. These have generally been of a more or less specialized character, and they have by no means exhausted the scope for further research. The appearance of two important new books on this subject is therefore a matter of considerable interest, particularly because both the original German edition of Zittel and the English translation by Mrs. Ogilvie-Gordon have long been out of print.

(1) The "Birth and Development of the Geological Sciences" was written during the author's retirement, after a lifetime of active geological work, and the story of how it came to be undertaken is worth telling. The fantastic theories put forward in past centuries to explain even the most commonplace of geological phenomena, such as the occurrence of minerals and fossils, aroused Dr. Adams's curiosity many years ago. Not content with reading about them at second-hand, he formed the habit of referring, when opportunity offered, to the original text of some of the more important early writers. Ultimately a growing interest in the subject led him to search out the works of other, less well-known authors. Thus, as time went on, he acquired an intimate knowledge of the byways as well as the highways in the early literature of natural science, in which are to be found the germs of present-day geological knowledge. In addition, in order to satisfy the necessity for repeated consultation of some of these early works, Dr. Adams, whenever possible, obtained copies for himself. In taking this course he followed, literally, the advice given as long ago as the fourteenth century by a very early booklover and collector, Richard de Bury, Bishop of Durham, which he quotes as follows, ". . . we secured the acquaintance of stationers and booksellers, not only within our own country, but of those spread over the realms of France, Germany and Italy, for no dearness of price ought to hinder a man from the buying of books, if he has the money that is demanded for them . . ." As a result, during the process of widening his knowledge of his subject, the author built up a specialized library, containing more than a thousand volumes in various languages, many of extreme rarity.

The belief, modestly expressed by Dr. Adams, that the knowledge derived from studies carried out during more than twenty years might prove of value to others unable to carry out such researches for themselves, fortunately induced him to prepare his notes for publication. The resulting book is, he explains, an attempt to trace the evolution of geological ideas from the first period of which we have any written record in Europe, that of the early Greeks, on through Classical Times, the Middle Ages and the Renaissance, down to about the year 1825, when geology as we know it to-day began its rapid development. The latter limit is not rigidly adhered to, since one or two chapters have been rounded off with a very brief outline of the later history of the particular subject dealt with, but no serious attempt has been made to discuss the period subsequent to this date.

The ground covered is indicated by the following list of chapter headings : bibliography and sources ; geological science in Classical Times ; the conception of the universe in the Middle Ages ; on the generation of stones ; medieval mineralogy ; the birth of modern mineralogy and its development from Agricola to Werner and Berzelius ; the birth of historical geology with the rise and fall of the Neptunian theory ; 'figured stones' and the birth of palæontology ; the origin of metals and their ores ; the origin of mountains ; earthquakes and the nature of the interior of the earth ; the origin of springs and rivers ; quaint stories and beliefs ; conclusion.

Dr. Adams makes the somewhat bold statement that few books likely to contain matter of real importance to his study remain unexamined by him, but after reference to the text no one is likely to dispute this claim, nor, indeed, the truth of the remark that his extensive reading proved the aptness of Bacon's aphorism, "Some books are to be tasted, others swallowed, and some few to be chewed and digested". Obviously some of the works consulted can have contained little that has a direct bearing on the subject, although, no doubt, they provided material to form the background essential for a proper appreciation of much that he has to say. Of this nature is the interesting chapter on the conception of the universe in the Middle Ages.

Dr. Adams deals more fully than previous authors with the ideas prevalent during the centuries preceding the emergence of geology as a separate branch of knowledge. It is impossible to refer in detail to the results of his researches into the early literature of science and natural history but I may mention one example. He discovered, and quotes at length, in translation, a hitherto almost unknown and exceedingly rare little book entitled "De Montium Origine". This was written by Valerius Faventies, and published at Venice in 1561, and, so far as is known, is the first treatise written in Europe dealing exclusively with the origin of mountains. Though its ideas are largely speculative, they are of interest, as Dr. Adams points out, in giving a picture of the manner in which a geological problem was approached in the later years of the sixteenth century. The treatise is cast in the form of a dialogue between two members of a party of friends, in a manner reminiscent of Boccaccio's "Decameron". Neither of the disputants gives any indication that he had ever climbed a mountain in his life, nor that he had any desire to do so. The days of geological field work had not yet dawned.

The formative years of geological science, the eighteenth century and the early years of the nineteenth century, are by no means neglected, and in dealing with this period Dr. Adams again quotes authors not referred to by either Zittel or Geikie, and other sources not available at the time these authors wrote, so that our knowledge of this period also is enlarged. The chapter on the birth of historical geology, for example, contains a particularly interesting and informative account of Werner and his doctrines.

Fortunately for his readers, Dr. Adams combines with a deep knowledge of his subject the ability to expound his store of knowledge in a charming and lucid style, and the result is a book that can scarcely fail to give pleasure to all who read it. Its attractiveness, too, is greatly enhanced by the inclusion of nearly one hundred illustrations, mostly reproductions from old scientific books. Yet the especial merit of this new history of geology is not merely that it is readable, or even that it adds so considerably to existing knowledge, but that the author has in every case gone back to original sources for his information. Thus, though his book does not supersede those of Zittel and Geikie, it must be regarded as the most authoritative work on the particular aspects of the subject with which it deals.

Unfortunately, a few small defects mar this otherwise excellent production. There are a number of typographical errors, some affecting the spelling of proper names, and others the dates of works to which reference is made. In addition, in one or two instances footnote references have been put in such a form as to cause difficulty in tracing the actual work to which it is intended to refer. Further, the value of the book as a work of reference would be correspondingly increased if the index were expanded.

Dr. Adams informs me that he intends to present his library to McGill University, where it will be housed in good company with the late Sir William Osler's collection of books on the history of medicine. It will then be known as the "Adams' Collection". A library of this type can only be built up after years of patient search, backed by adequate knowledge and sufficient means. It is welcome news, therefore, that Dr. Adams's unique collection is not to suffer dispersal, the fate of many important private libraries. Its value will be better appreciated after publication of the catalogue, on which the author is at present engaged.

(2) Opportunities for reading original texts of the type so largely represented in the Adams Collection are few. Many are written in Latin, and of these only a small number have been translated into any modern language; and, in any event, they are seldom accessible to the average reader. Those who may wish to consult works of this sort will be interested to learn that their needs have now been met, to some extent, by the publication of Mather and Mason's "Source Book in Geology".

This is the fourth in a series of "Source Books in the History of Science", published under the general editorship of Gregory D. Walcott and an advisory board of American men of science, assisted by special committees for each science. The enterprise has also received financial aid from the Carnegie Corporation of New York. The object of these "Source Books" is to make readily accessible the significant passages from the works of the most important contributors to the major sciences during the last three or four centuries, up to the end of the nineteenth century. Each therefore consists of a large number of quotations, carefully selected with as much finality of scholarship as possible. These are given in English translation when necessary, a decided advantage in the latest volume, in which nearly half the extracts were originally written in languages other than English.

In this volume the term 'geology' has been interpreted in its widest sense, and twenty-nine separate divisions of the science are represented. The compilers, in choosing their material, have attempted to strike a balance between the needs of readers interested in the science as a whole, and those of students concerned only with a particular branch of the subject. Preference has been given, where other considerations are nearly equal, to excerpts from sources least likely to be accessible to the majority of geologists.

The scope of the book may be judged from the fact that it includes three hundred and twenty-nine extracts from more than one hundred British, Continental and American authors, ranging in time from the fifteenth to the end of the nineteenth century. Contributions to geology made since 1900 have not been included, nor those by living authors. The excerpts are, in general, arranged in chronological order according to the date of birth of the authors, and a subject index is provided.

The task of compiling this book must have entailed an immense amount of literary research. Of its kind it is a pioneer work, and it may be said at once that the task has been well done. It is unlikely that complete agreement could have been obtained among the many collaborators as to the final selection of authors whose work should be quoted, and, in fact, this is hinted at in the preface. The compilers, however, accept responsibility for the final choice. In glancing through the pages of the book, one is struck more by the number of names included, many well known, others unfamiliar, than by the few questionable omissions. Yet a few names outstanding in the history of geology are missing. Among these may be noted that of Palissy the Potter, whose observations on fossils, made in the sixteenth century, it would have been interesting to read. The work of Lehmann and Füchsel, too, who made important stratigraphical observations in the eighteenth century, might well have been included. The original writings of these authors are to be found in very few libraries. In contrast, extracts have been given from the works of men of science not usually associated with geology, such as, for example, Robert Boyle. His observations on the conditions prevailing at the bottom of the sea, though of interest, are not original, and can scarcely be said to have had much influence on the development of geological thought. Cavendish, too, was not primarily a geologist, but, with more justification, an extract has been given from the account of his experiments to determine the density of the earth by means of the torsion balance. In reading this account, one is reminded of the interesting fact that this instrument of precision, now the tool of the geologist and prospector as well as the physicist, was actually invented by a geologist, John Michell, in the eighteenth century.

Though, perhaps, to be regarded primarily as a work of reference, this is a book into which any geologist can dip with the expectation of finding something to interest him. It forms a valuable supplement to the existing histories of geology, and the compilers are to be congratulated on the thorough and painstaking manner in which they have carried out their task.

The literature on the early history of geology has been greatly enriched by the publication of the two books reviewed above. Dr. Adams has, dealt fully with the long period ending in the early years of the nineteenth century, and Mather and Mason record the chief landmarks in the history of the science from the fifteenth right up to the end of the nineteenth century. The detailed story of the development of geology during the last hundred years, a period of great expansion in every branch of the subject, still awaits an author.

V. A. EYLES.

THE GOLGI APPARATUS

Form- und Stoffwechsel der Golgi-Körper
Von Gottwalt Christian Hirsch. (Protoplasma-Monographien, Band 18.) Pp. xi+394. (Berlin: Gebrüder Borntraeger, 1939.) 28 gold marks.

THE author of "Form- und Stoffwechsel der Golgi-Körper" attracted attention by his papers published in 1931, in which he claimed that the zymogen granules of the pancreas acinus cells originated not inside the Golgi apparatus, but drifted into that position from the base of the cell, where they originated in contact with the mitochondria.

Dr. Hirsch's claim was examined in my laboratory by E. S. Duthie in 1933, who agreed that very small granules were continually drifting across the cell into the region of the Golgi apparatus, where they swelled into zymogen. It cannot be said that Dr. Hirsch's work has been received everywhere with warmth among those cytologists who believed that practically all cell secretion granules originated inside the Golgi apparatus. Recently a strong attack on Hirsch and Duthie's work has been made in the *Quarterly Journal of Microscopical Science* by the competent Indian cytologist, Dr. Subramaniam, as a result of his investigation on the endostyle of *Branchiostoma indicum.* Nevertheless, Dr. Subramaniam fails to show what connexion the zymogen granules in the pancreas of the mouse have with the secretion of mucus in Branchiostoma, and as matters stand at present Dr. Hirsch's results must be accepted.

Following his interesting work on the pancreas, Dr. Hirsch has now written a book on the Golgi apparatus. He has read 2,000 papers on this subject, and appears to be convinced that there is such a thing as the Golgi apparatus. Furthermore, most of his ideas on the actual structure of the Golgi apparatus will be generally acceptable to British and American cytologists.

As is natural, the book deals more fully with the histological aspect of the subject, but Dr. Hirsch has interesting sections on spermatogenesis and oogenesis. One astonishing point about Dr. Hirch's book is the calmness with which he endeavours to harmonize the very different and apparently incompatible results of cytologists who have been sharply at variance in recent years. But Dr. Hirsch has tried to provide a view of this confused subject which might show the results of the workers of all countries in the best light, and he has certainly succeeded in this object very fully. Indeed, it could have been said in happier times that his book would have been certain to have inspired many of the younger zoologists and physiologists to undertake their life's work in this branch of cytology.

It is pleasant to read that Dr. Hirsch accepts the nature and homology of the plant osmiophilic platelets (Golgi bodies) discovered by the American cytologist, the late Robert Bowen. Dr. Hirsch dedicates his book to the curators of the University of Utrecht in gratitude for the opportunity given him of working there.

Dr. Hirsch's book, and the interesting researches of W. Jacobs, W. Buchmann, E. Ries, L. H. Bretschneider, J. W. Sluiter, O. Järvi and many other young Dutch cytologists, bear witness to the very valuable work now being carried out at Utrecht under his leadership.

J. BRONTË GATENBY.

CAPTAIN JAMES COOK, R.N., F.R.S.

The Life and Achievements of Captain James Cook, R.N., F.R.S.
Explorer, Navigator, Surveyor and Physician. By Surgeon Rear-Admiral John Reid Muir. Pp. vii+310+16 plates. (London, Glasgow and Bombay: Blackie and Son, Ltd., 1939.) 10*s.* 6*d.* net.

THE consideration of Cook as the 'physician' rather than the astronomer, surveyor and explorer well deserves this pleasant story. It is the central theme, which the author is well qualified to undertake, in the summaries of his three voyages, to the neglect of much consideration of their value to scientific knowledge; however, his bibliography is so short that more cannot be expected. Cook served his apprenticeship in small colliers trading along the English coasts. He chose similar ships for his voyages, and his knowledge of their capabilities was a large element in his success. His observations on the eclipse of the sun as seen in Newfoundland in 1766 caused him to be appointed by the Royal Society as its chief observer of the transit of Venus viewed afterwards from Tahiti in June 1769. A further object was the discovery of the great southern continents, a current myth at that period, the second expedition having this as its main objective; the third was primarily concerned with the North-West Passage. Cook everywhere found new lands, and nearly every chart of the Pacific is headed by his name. His running survey of New Zealand, which he completely circumnavigated, causes him to be regarded as the leader and greatest of that line of surveyors that has made the Navy famous. This had been especially brought out by the late hydrographer, Admiral Sir W. Wharton, in his studies of Cook, the error in the longitude of the observation station at Tahiti being only two minutes. That Cook attained international fame during his life is seen in that France, the United States, Spain and Russia extended to his third expedition a safe conduct in that war period.

Even the most careful research has yielded little knowledge of the character of Cook, while nothing is known of his domestic life. We judge that he was a reserved and lonely individual. That he was a personality with the necessary power of command is clear, in that the Admiralty gave him *carte blanche* in selecting his stores and crew. Among seamen his reputation was such that he had not to resort to the press-gang and to jailbirds, thus avoiding the danger of typhus then so rife. The result is seen in that his ship was not the prison as naval vessels were usually in those days, shore camps being established and leave frequent.

The great danger was scurvy, and long voyages often had to log a death-rate of 50 per cent or even more. The best authenticated case is Anson's voyage round the world in 1741, in which out of crews numbering 961 more than two-thirds died of scurvy, and on the homeward voyage only 71 were able to stand to their guns. Everywhere Cook's first care was water, which was never rationed; this an essential of a salt-meat diet. Every land was searched for scurvy grass, wild celery and other vegetable products, while fresh meat was purchased wherever possible. The strictest cleanliness was enjoined, Cook inspecting his crew twice weekly, while their quarters were ventilated and fumigated weekly, a proceeding recommended by Dr. Lind in 1753. It was forty years later that the Admiralty commenced the issue of lime juice, which has no antiscorbutic vitamins, a tragic error due to a confusion of names (lemon *v.* lime) that persisted for more than a hundred years. Cook largely relied on portable soup made of desiccated meat and bones, greens stored with salt which was termed "sour kraute", malt and beer concoctions, while fresh meat was everywhere sought. The results are well seen in Cook's voyages, as in all three the loss from scurvy was negligible, far less than that from Batavian dysentery and malaria while repairs were being carried out on the *Endeavour*.

TRIGONOMETRICAL TABLES WITH THE ARGUMENT IN TIME

Seven-Figure Trigonometrical Tables for Every Second of Time

Prepared by H.M. Nautical Almanac Office. (Published by order of the Lords Commissioners of the Admiralty.) Pp. 102. (London: H.M. Stationery Office, 1939.) 10*s.* 6*d.* net.

COMPUTERS are well aware of the difficulties experienced in dealing with right ascension, hour angle, etc., in astronomical work, when trigonometrical functions of these are required. It is necessary to convert them into degrees, minutes and seconds of arc before tables of trigonometrical functions can be used, and tables with the argument in time have been in demand for many years. The present volume supplies a need and is the first seven-figure table to be published which gives the four natural trigonometrical functions chiefly used in astronomy and related sciences, intervals of one second of time being used throughout.

The preparation of the tables was completed about twelve years ago under the direction of Dr. L. J. Comrie, formerly superintendent of H.M. Nautical Almanac Office, but approval for publication was not obtained until 1932, and the printing has been delayed for various reasons. Manuscript tables have, however, been in use in the N.A. Office for about seven years, and the table of tangents has been utilized in the computations of the right ascensions of the sun, moon and planets.

Seven decimals have been retained except in the cases of the cotangent. Here the number of decimals depends upon three desiderata: (*a*) linear interpolation; (*b*) the same number of significant figures as the tangent; (*c*) sufficient figures to enable inverse interpolation to give a mean accuracy of 0·001s., but as the first and third of these cannot both be satisfied everywhere, the scheme adopted is based mainly on (*b*). In some cases values of the cotangent to more decimals than are tabulated or to more than can be easily interpolated, are required, and to meet this need there is an auxiliary table containing the function $\tau = x^s \cot x^s$ to three decimals, for every second of time up to 30m. Eight significant figures can be obtained from this table by simple interpolation, and the cotangent or tangent can then be derived to seven significant figures by simple division. In both tables the greatest and least differences in any column are given at the head and foot of each column, no interlinear differences being given, and this arrangement enables the complete difference to be obtained from an inspection of the end figures.

The table is naturally intended for use with a computing machine, and computers are recommended to utilize the methods of direct and inverse interpolation which have been explained very fully in the "Nautical Almanac" for 1937, and reprinted in "Interpolation and Allied Tables" (H.M. Stationery Office, 1936). It should be added that the printing and reading of the proofs have been carried out under the direction of the present Superintendent of the Nautical Almanac Office.

M. D.

VIRUS RESEARCH

Methoden der Virusforschung
Von Prof. Dr. Henrique da Rocha-Lima, Dr. José Reis und Dr. Karl Silberschmidt. Pp. viii + 384. (Berlin und Wien: Urban und Schwarzenberg, 1939.)

FOR years the study of viruses was closely linked with bacteriology and mycology, descriptions of viruses occupying only minor parts of books devoted mainly to bacteria and fungi. This followed inevitably from the widely held belief that viruses differed essentially from other recognized pathogens only in size, and from the fact that they were investigated almost exclusively by a few enterprising bacteriologists and mycologists. Recently, however, the outlook has changed. A growing appreciation of the economic importance and scientific interest of viruses has attracted workers in other fields, and the need for separating viruses from other pathogens has become more and more obvious. One result of this has been the increased production of books dealing exclusively with viruses, of which that under review is the fifth to appear within two years.

In many ways this book differs from those previously published. One advantage it has is that the subject is treated as a whole. No gross distinctions are made between viruses attacking animals, plants and bacteria, all of which are dealt with under the same general headings, the book being kept to a reasonably small size by the omission of details of disease symptoms. A disadvantage is that the authors neither discuss controversial points nor criticize the work they describe. However, it is more than the description of techniques suggested by the title, for full details of the results obtained are also given, and, with one qualification, it is fairly described as a good, impersonal summary of experimental work on viruses. The gathering together of so much work published in a large number of apparently unrelated journals will be useful to most workers, but will probably be of greatest value to those who have not ready access to good library facilities.

The book is divided into three main sections, dealing respectively with viruses in diseased organisms, infection methods, and the properties of viruses *in vitro*, of which the last occupies about two thirds of the whole. The techniques described range from the construction of insect-proof glass-houses and the culturing of insect vectors, through such subjects as transmission, ultra-microscopy, ultra-filtration, centrifugation, cataphoresis, and serology to tissue culture and the culturing of viruses in developing eggs. Nevertheless, in spite of the variety of methods described, all those used in work on viruses are not included. This is, no doubt, a direct reflection of this book's greatest fault, which is that it is already out of date. Except for a short supplement containing references to a few papers published in 1938, the last papers referred to were published early in 1937. As a result, not only are the many advances made in the last three years excluded, but often undue prominence is given to methods that would no longer be used.

The illustrations are all line drawings and, although some of these may be an aid to the text, it is difficult to see what is gained from the inclusion of others, such as Figs. 1, 31, and 51. As the book is presumably meant as a laboratory handbook rather than one to be read, it is a pity it is not better bound, for it is unlikely that the flimsy paper cover and the loose stitching will withstand much handling.

F. C. BAWDEN.

OUTBREEDING AND SEPARATION OF THE SEXES

BY DR. K. MATHER,

JOHN INNES HORTICULTURAL INSTITUTION

GAMETIC DIFFERENTIATION AND SEPARATION OF THE SEXES

THE process of sexual reproduction shows two remarkable features, namely, that in all but some of the lowest organisms there is gametic differentiation, the male and female gametes being morphologically and functionally distinct, and that there is, in some plants and most animals, separation of the sexes, the two kinds of gametes being produced by different unisexual zygotes.

The former phenomenon may very reasonably be interpreted as showing a division of labour. The female gamete is larger and contains, or is associated with, food stores, which may be utilized by the developing embryo, while the small male gamete is more motile and seeks out the less active egg prior to fertilization. Such a division of labour would appear to have a selective advantage and so would be favoured.

The reason for the separation of sexes is, on the other hand, not so easy to understand, more especially as it is far from being a universal property of sexual reproduction. A number of arguments have been put forward seeking to account for the known facts, and nearly all of them, in some way or other, relate unisexuality to differentiation of the gametes. Two fairly recent examples may be mentioned.

Waddington[1] discusses the phenomenon in the following words: "Probably, then, the original mechanism [of sex determination] was an alternative mode of reaction in the gamete itself. . . . Usually, however, the time at which the alternative is decided is pushed further back in the life cycle, probably on a safety first principle. Eventually, in the higher animals and plants, the sex determination of a gamete has been pushed back to the fertilization of the zygophase before". The sexes are separated supposedly in order to ensure that the gametes are differentiated.

In the higher plants, however, separation of the sexes is sporadic rather than regular, although the gametes and their associated tissues are as successfully differentiated, morphologically and functionally, as in animals. Furthermore, in certain plants and animals the sex of a unisexual individual may be controlled environmentally though its gametic differentiation is perfect and regular. Nor should gametic differentiation itself be regarded as a necessary part of sexual reproduction. Many Thallophyta have successful sexual reproduction with no differentiation, or, at least, no morphological differentiation of the gametes. Thus sexual separation can scarcely be considered to be merely a predetermination of gametic differentiation, though this aspect may, of course, play some part in the evolution of the diœcious state. Any hypothesis seeking to account for unisexuality in most animals must also provide a reason for the widespread hermaphroditism in plants.

Altenburg[2] has advanced a different view. He notes that hermaphroditism is related to sluggishness and sessility. Then by means of a highly ingenious argument he concludes that the monœcious and diœcious states are adapted to the minimization of the work involved in reproduction. Thus insect-pollinated plants are, he claims, all hermaphrodite, as they need expend little work in the production of male gametes, the insect ensuring that the pollen is transferred to a stigma; so they can distribute the reproductive load evenly between individuals only in this way. Wind-pollinated plants, on the other hand, expend relatively more energy in the production of pollen, much of which is lost in the air, and, the male and female loads being more nearly equal, they may as economically be diœcious as monœcious.

A similar argument is advanced for sessile and motile animals. Sessile forms have, like wind-pollinated plants, a large male load and so are indifferently hermaphrodite or unisexual. Motile animals may minimize the expenditure on sperm production by transference following coition, and so should be analogous to insect-pollinated plants. They are, however, unlike the plants in that they are not in general hermaphrodite. The reason given for this is that they overcome the difference in male and female reproductive loads by polygamy, sexual dimorphism and sexual differences in life-span.

There are a number of objections to this argument. In the first place, it is not clear why freely motile animals should be hermaphroditic less often than sluggish ones, when insect-pollinated plants are supposedly less often unisexual than anemophilous forms. In the second place, Altenburg goes too far in supposing that all insect-pollinated plants are hermaphrodite. *Silene Otites*, *Melandrium dioicum* and *Rubus Chamæmorus* are examples of diœcious entomophilous forms. Whether separation of the sexes is actually less common among insect-pollinated species is difficult to say as the available records are not always trustworthy, though some such correlation is suggested (cf. Lewis[3]). Finally, it is far from certain that wind-pollinated plants do in general produce more pollen per seed set than do insect-pollinated ones. Extreme examples of excessive pollen production by both kinds of plant could be cited, but it is doubtful whether statistics adequate to settle the question have been obtained. The same may be said of sperm production by animals. Until these objections have been successfully met, Altenburg's hypothesis cannot be accepted without crippling reservations, though it may be applicable to special cases.

SEXUAL REPRODUCTION AND SEPARATION OF THE SEXES

There is, however, another approach to the question which helps to make clear the reasons for sexual separation occurring in some cases and not in others.

First of all, it is necessary to dismiss the developmental-genetic idea that separation of the sexes is of necessity related to gametic differentiation. Such differentiation has its own function in relation to nutrition of the ensuing zygote and is present, often in an elaborate form, in both hermaphroditic and unisexual organisms. The morphological analogy between gametic and zygotic differentiation is only misleading.

There is, however, one inevitable consequence of the diœcious state which enables us to understand its occurrence. If the sexes are separate, fertilization must always involve gametes from different zygotes and, in the vast majority of cases, these zygotes must be genetically distinct. It is essentially a mechanism for the promotion of outbreeding.

Now the importance of sexual reproduction to living organisms is that by its aid a higher degree of hybridity and effective recombination may be achieved than would be possible with purely asexual propagation. An increase in the effective recombination allows of a more rapid response to the action of natural selection (Fisher[4], Muller[5], Darlington[6]). Thus outbreeding is an essential feature of sexual reproduction in that it necessarily leads to greater hybridity and so, ultimately, to a greater response to selection, than does inbreeding. It is not clear that the maximum advantage will always follow from maximum outbreeding. On the contrary, there is some evidence that species have an optimum degree of hybridity, which optimum may depend on the environment. This question is, however, too complex and uncertain to be given detailed consideration here. It is sufficient to note that outbreeding is an essential part of sexual reproduction.

It is, then, easy to see that unisexuality is of advantage by virtue of its ensuring some degree of outbreeding, and hence its occurrence is a simple adaptation for the more successful results of sexual reproduction.

There are, however, other mechanisms which will achieve the same purpose. Incompatibility is found in Angiosperms and the Fungi, and also most probably in the sea squirt *Ciona*. In the Fungi it apparently depends on the aversion of the haploid hyphæ, and in the Angiosperms on a rather complex relation of the pollen tube and stylar tissue. The genetical basis of incompatibility varies, though in Angiosperms it is usually of the type first described in *Nicotiana* by East. A related mechanism is that of illegitimacy found, for example, in *Primula* and *Lythrum*. It differs from incompatibility in that it is dependent on the genetical relations of the zygotes bearing ovule and pollen, and not on the genetical relations of male gamete and female zygote. These species, together with others, also show heterostyly, which presumably encourages crossing, though the efficacy of this mechanical method is open to doubt, as it is so frequently accompanied by an incompatibility or an illegitimacy mechanism. Protandry, protogyny, special floral arrangements and other devices could also be listed.

Now these various methods, though widespread, are rarely, if ever, found where the sexes are separated. They are alternatives to unisexuality. So our conclusion that the separation of sexes is simply a method of encouraging cross-breeding is strengthened, as such encouragement is the only effect common to all these mechanisms.

DISTRIBUTION OF OUTBREEDING MECHANISMS

If we are to regard unisexuality simply as one of a number of outbreeding mechanisms, it is necessary to account for the fact that it is frequently found in some groups, for example, the higher animals, but rare in others, for example, the higher plants, being often replaced in the latter case by one or other of its alternatives.

To understand this, let us compare the action of unisexuality and incompatibility. In a diœcious species an individual can cross with only a portion of the remaining population, namely, those of the other sex. Unless some way is available whereby each individual of at least one sex can seek out a member of the other sex with which to mate, so ensuring that its gametes are not wasted, there must be a large loss of reproductive energy due to maldistribution of the gametes. In most animals such wastage is, however, much reduced by the presence of such a discriminatory mechanism whereby the motile male seeks out the female and transfers sperm directly to the egg by coition. This cannot be done in higher plants.

The incompatibility mechanism is superior to unisexuality in that it leads to less gametic loss where indiscriminate mating prevails. In the *Nicotiana* type of behaviour, pollen only fails to function when it falls on to the stigma of a plant carrying the same allelomorph of the incompatibility gene as does the pollen itself. There may be a very large number of such allelomorphs. More than a hundred have been found in wild *Trifolium*. The actual gametic loss is inversely proportional to the number of allelomorphs and so may be very small. Hence the incompatibility mechanism has an advantage over unisexuality where no discriminatory mating is possible. On the other hand, no easy mechanism, such as mobility, can be developed to assist discrimination where so many genetic classes are involved. So unisexuality with discrimination may exceed incompatibility in efficiency, in the case of motile organisms, where the loss due to unisexuality can be reduced effectively to zero. Furthermore, there must be some mechanism for sorting out incompatible male gametes before they meet the egg, or otherwise loss of female gametes may result. This is done in the higher plants by the stylar tissues, but it would not be possible in most animals where fertilization takes place in a duct or in open water.

Hence it can be seen that there is a reasonable explanation for motile animals depending mainly on unisexuality while higher plants usually adopt incompatibility or an analogous system of gametic discrimination. In the former case, wastage from separation of the sexes is reduced by means of mate discrimination, whereas an incompatibility mechanism would be difficult to operate. In plants, mating discrimination is difficult but incompatibility easy to operate.

The above remarks about incompatibility apply equally well to the closely allied illegitimacy mechanism. The other outbreeding devices found in plants may also be considered in a similar way. Protandry, for example, discourages self-pollination in the same flower, where its risk of occurrence would be greatest, while ensuring that the rest of the population are capable of receiving the pollen after its release. It is not, however, a fool-proof device for securing outbreeding.

Thus unisexuality may be regarded as one of a number of devices which arise by reason of their encouragement of outbreeding. The one to be adopted in a particular species depends on its special features, though the most suitable mechanism may not always develop. Thus if the disadvantage of wastage following on separation of the sexes in a plant is less than the advantage gained by the encouragement of outbreeding, unisexuality might occur but would be liable to be weeded out as soon as environmental conditions reversed the magnitudes of these opposite effects. So the diœcious state is a transient feature of some Angiosperms. It is also clear that some species which are in a stable environment, to which they are highly adapted, may find recombination a disadvantage and so suppress outbreeding mechanisms or even substitute inbreeding adaptations as in *Pisum* and *Triticum*, where premature anthesis vitiates a highly developed crossing mechanism. This is easier to do where the sexes are not separated. 'Fertility' allelomorphs are, for example, known at the incompatibility loci of many plants which normally show this particular outbreeding mechanism. But to reconstitute hermaphrodites from highly developed unisexual species would seem to be more difficult. Hence inbreeding mechanisms are commoner, or at least more obvious, in plants than in animals. The marked sexual dimorphism of animals, developed as an ancillary arrangement for the more effective operation of the outbreeding mechanism, has prevented a return to hermaphroditism in any special cases where inbreeding would be desirable, except by the adoption of extreme devices, as in *Pediculus*.

Gynodiœcy should not be confused with unisexuality in this connexion. It resembles unisexuality in that a proportion of the individuals are female, but differs in that the remainder are hermaphrodite, not male. Clearly the females are at a disadvantage as compared with the hermaphrodites, since they produce but one kind of gamete. Hence gynodiœcy will only survive where the females enjoy some compensating advantage, which is most likely to depend on the outbred nature of their offspring. My colleague Dr. Lewis has shown[3] that the equilibrium proportion of females is directly dependent on the magnitude of this advantage ; so such gynodiœcious species have a ready means of adaptation to change in the hybridity optimum. The proportion of females and so of outbreeding increases with increasing advantage of hybridity and decreases as the advantage of hybridity decreases. Thus gynodiœcy, unlike unisexuality, is a highly adaptable outbreeding mechanism.

A NATIONAL ATLAS OF BRITAIN

By PROF. E. G. R. TAYLOR,
BIRKBECK COLLEGE, LONDON

WITHIN a few days of the appearance in NATURE of an article upon the proposed National Atlas[1], an afternoon meeting of the Royal Geographical Society devoted to a discussion of the project was opened by the present writer as chairman of the National Atlas Committee. A verbatim report of the proceedings appears in the current (February) number of the *Geographical Journal,* but since the discussion has already borne practical fruit, and since further arguments for pressing forward with the Atlas have been provided by public events, it appears that a useful purpose will be served by examining the points upon which agreement has been reached.

Prof. Kenneth Mason, chairman of the meeting, recalled that the urgent need for a National Atlas was first realized when the Society was asked to give evidence before the Royal Commission on the Geographical Location of Industry and of the Industrial Population. A portfolio of maps was laid before the Commission, including many that were then drawn for the first time, as, for example, the actual distribution of the industrial (as opposed to the general) population, the pattern of unemployment distribution, and maps showing the relative accessibility by rail of the principal towns of England and Wales in terms of time. Accessibility was a point stressed also by a road map on which was indicated the degree of likelihood of interruption of traffic by snow. This particular map, based though it was on the specialized knowledge of Mr. L. C. W. Bonacina and Mr. Gordon Manley, was rather sceptically received, yet the warnings that it conveyed and the silent advice that it offered have been abundantly justified during the present winter. Indeed, it is not too much to say that had this series of maps been consulted, the selection of centres for the location of reserve stocks of food and fuel, and the choice of boundaries for supply regions, could have been made far more efficiently than has seemingly been the case. The excuse so often made by the responsible authorities that not shortage of supplies but delays and difficulties of distribution are responsible for deprivation and distress is one that demands probing.

It is noteworthy, however, that in their recently published report, the members of the Royal Commission put on record their appreciation of the usefulness of the maps placed before them, and their intention of publishing some of them in a later volume. Should the recommendations of the Commissioners be implemented, then the strength of the arguments for a National Atlas must prove irresistible, for it would provide an obviously useful, even indispensable, adjunct to "Collection and co-ordination of information relating to location of industry, now in the possession of the various government departments", to "Research; and collection of information as to the various natural resources—land, agriculture, amenities, etc.—that may be affected by industrial location", to name but two of the tasks with which the proposed new Central Planning Authority would be charged[2]. Moreover, with the National Atlas lying open at the appropriate page, chapter and verse could be given for the "Advice to government, local authorities and industrialists as to problems of location' which the Central Planning Authority would be empowered to offer[2].

It is indeed the case, as the general discussions at the British Association and at the Royal Geographical Society have shown, that, in principle, the plea for a National Atlas finds general acceptance. Nevertheless, an actual Atlas might well fail to achieve usefulness on three or four counts, as, for example, if the information it contained was not entirely reliable or up to date, if the style of the maps was too academic or otherwise unsuited to the general public, if the price of the Atlas put it beyond the reach of all but well-to-do individuals and public bodies.

On all these points the latest discussion has provided information and advice of positive value. In the first instance it is clear that despite the generously offered co-operation of scientists, the Atlas would fail of its object if access could not be secured to official statistics before their publication in Blue-book form. This is essential, not only to avoid a double time-lag, but also because the methods employed in grouping statistics for tabulation often render them unsuitable for plotting on a map. The obvious corollary is that the Atlas must have official status, since such facilities could not be granted to a commercial firm or to private persons.

In respect of the style of the maps, there need be little apprehension, since the long experience and exceptional technical skill of the Royal Geographical Society's drawing-office is generously placed at the Committee's disposal for experimental work. Nevertheless the discussion brought out an important possibility which had perhaps been overlooked. It was pointed out that the Atlas would undoubtedly be drawn upon frequently for newspaper maps, maps to illustrate articles and lectures, lantern-slides and the like, so that it would be very desirable to bear in mind what would be the appearance of a photostat copy or half-tone block made from any Atlas map: significant detail printed, for example, in blue would, of course, be lost. It is here perhaps not irrelevant to note that the secretary of P E P (Political and Economic Planning) in a written reply to a criticism by the writer of the weak and faulty map illustrations in that body's recent memoir on Location of Industry, took up the point of view that economists did not profess competence in cartography and would welcome a reliable source from which illustrative maps could be obtained at will.

The question of how to make a National Atlas accessible at relatively small cost to all those requiring to use it has not been lost sight of, and there has been a general consensus of opinion that the Atlas should be published serially as and when individual maps or groups of maps are completed. The Director General of the Ordnance Survey, speaking from his unrivalled knowledge of the distribution to the public of national maps and plans, expressed the view that the sale of single sheets should be made possible, thus allowing many people to participate cheaply in the benefits the Atlas could afford to their particular interests. As another speaker remarked, motorists, salesmen, publicity agents, and many others might require the maps dealing, for example, with transport, amenities, or industrial location, while they would have no interest in maps of fisheries, geology, and the like. On the production side, the sale of single maps might introduce difficulties, but there is no doubt of the importance and the feasibility of the second suggestion coming from Major-General Macleod, namely, that the Atlas should be 'tied' to the series of national plans and surveys (the ordnance maps) by the adoption of the metric grid recommended by the Davidson Committee. By the use of a suitable projection, and by substituting the rectangular lines of the grid for the curved and converging lines of the ordinary graticule, a basic source of difficulty, confusion and error to which the non-geographical map user is prone is at once removed. The position of any point can be exactly determined, and since it is proposed to place an identical grid on all the maps in the National Atlas irrespective of scale, a means of accurate enlargement or reduction is immediately at hand when it is required to make comparisons between maps on different scales. The original plan to make the one to a million scale the basic scale of the Atlas has been seriously challenged on two grounds: that it would make the Atlas as a whole too heavy and bulky to handle, besides the individual sheet being too large for the ordinary desk or table, and that it would require the use of sheets of paper of unusual size which would greatly increase the prime cost. Experiment has proved that a scale of 1 : 1,250,000 for the largest map, that of England and Wales, obviates both these disadvantages, disadvantages which would so repel the public which it is desired to reach, that they must be eliminated at all costs.

It is pleasant to be able to record that funds are in sight for the printing and distribution of numbers of blank base maps on which individual scientists will be invited to plot their contributions. When a sufficient number of such manuscript maps is in hand, it is confidently expected that they will provide in themselves convincing arguments for that official approval and for that public or private financial support which, once secured, will quickly bring a National Atlas into being.

THERMODYNAMICS AND THE STRUCTURE OF MATTER*

By A. R. UBBELOHDE,
ROYAL INSTITUTION, LONDON

THE equilibrium positions of atoms and molecules in condensed phases are the result of an interplay between the forces of repulsion and attraction, and the thermal motions in the substance. This explains why thermodynamic considerations can make important contributions to theories of the structure of matter. Advances in the knowledge of various crystal structures have, on the other hand, led to considerable progress in thermodynamics.

One of the properties of crystals illustrating this statement is the 'lattice energy', which can be defined as the heat of sublimation at absolute zero. The intermolecular forces[1] that lead to phenomena such as deviations from the perfect gas equation, capillary and adsorption processes, and the broadening of spectral lines, also lead to the arrangement of all molecules in regular crystal lattices at sufficiently low temperatures. In different crystal lattices, repulsive forces nearly always arise from a common cause, namely, the interpenetration of electron clouds around individual atoms. For discussing energetics, crystals are therefore best classified according to the predominant force of attraction. The highest lattice energies are observed when the predominant force is due to covalency (for example, diamond, 135 kcal./mole), or electrovalency (for example, common salt, 181 kcal./mole). A special case of electrovalency arises for metal lattices, in which the negative ions are electrons, the small mass of which leads to special quantum-mechanical forces (for example, sodium, 26 kcal./mole). When the predominant attraction is due to permanent dipoles, the lattice energy is considerably smaller (for example, ammonia, 7 kcal./mole). If hydrogen atoms are present in the crystal, the close approach of the hydrogen atom, forming part of one dipole, to another polar atom, may lead to 'hydrogen bonds'[2]. Finally, the predominant attractive forces may be due to polarization. In rare but interesting crystal lattices such as chlorine hydrate, $Cl_2.8H_2O$, and krypton hydrate, $Kr.6H_2O$, the non-polar chlorine and krypton are polarized chiefly by the permanent dipoles of water. Polarization due to zero point motion of the electrons around each atom leads to the much commoner 'dispersion forces', such as predominate in the crystal lattices of inert gases and non-polar hydrocarbons.

---

* Based on a course of lectures delivered at the Royal Institution on November 1, 8, 15 and 22.

In principle, the experimental measurement of lattice energies would involve a determination of the heat of sublimation at any one temperature, followed by extrapolation to absolute zero, using the specific heats of crystal and gas. Lattice energies are, however, seldom known with sufficient accuracy at present to give full significance to this correction. This is partly due to the fact that the vapour pressure of most crystals is too low to permit a direct calorimetric measurement of the heat of sublimation. Numerous indirect determinations depend on two thermodynamic rules:

(1) The Clausius Clapeyron equation, which states that the heat, $\triangle H$, absorbed in any change of phase can be calculated from the volume change, $\triangle V$, and the temperature coefficient of the equilibrium pressure, P, according to the formula $\triangle H = T \triangle V(dP/dT)$;

(2) Hess's Law, which states that the total heat required to proceed from any state A to a state B of the system does not depend on the intermediate route.

The first of these rules is commonly applied in evaluating heats of sublimation from vapour pressure curves. Manometric measurements of the vapour pressure are only possible for a few solids, such as carbon dioxide, but for solids with low vapour pressures the effusion method[3] has been used. A lattice energy of great importance is that of solid carbon, which has been tentatively evaluated from vapour pressure measurements on carbon arcs[4]. The Clausius Clapeyron equation is also used in calculating the lattice energy of polymorphs stable at high pressures[5].

An important example of the use of Hess's Law is presented by ionic lattices, for it is difficult to make direct measurements on changes of the type

$$\underset{\text{solid}}{[\text{NaCl}]} \rightarrow \underset{\text{gas}}{(\text{Na}^+)} + \underset{\text{gas}}{(\text{Cl}^-)} + 181 \text{ kcal.}$$

In this example, the heat of sublimation is calculated by summing the successive steps:

$$\underset{\text{solid}}{[\text{NaCl}]} \xrightarrow{+99\text{ kcal.}} \underset{\text{solid}}{[\text{Na}]} + \tfrac{1}{2}\underset{\text{gas}}{(\text{Cl}_2)} \xrightarrow{+53\text{ kcal.}} \underset{\text{gas}}{(\text{Na})} +$$

$$\underset{\text{gas}}{(\text{Cl})} \xrightarrow{+29\text{ kcal.}} \underset{\text{gas}}{(\text{Na}^+)} + \underset{\text{gas}}{(\text{Cl}^-)},$$

for which the heat changes are obtained by calorimetry,. vapour pressure determinations, or spectroscopic measurements[6]. An obvious weakness is that errors in the various steps may be cumulative.

Theoretical calculations of lattice energies aim at correlating crystal structures with heats of sublimation, and other properties of the crystal, and have met with considerable success in suitable cases[7].

As the temperature of a crystal lattice rises above 0° K., it acquires various forms of thermal energy. The contribution due to lattice vibrations is best considered separately, before discussing the contribution due to other 'modes of motion'. Among the phenomena which give fairly direct information about the lattice vibrations in various crystal structures are the specific heat, the temperature variation of the intensity of X-ray reflection from various crystal faces, and the thermal expansion.

In the region of temperatures where the law of Dulong and Petit applies, the specific heat is independent of crystal structure. At lower temperatures, the specific heat falls off, and Einstein was the first to calculate the vibrational energy E of crystals in terms of a single frequency ν, characteristic of crystal structure, obtaining the well-known expression, for a crystal of N atoms,

$$E = N\,[h\nu/(e^{h\nu/kT} - 1)].$$

A consideration of even simple models shows, however, that the thermal motions of atoms in a lattice must be interdependent, or 'coupled'. More complete theories of lattice vibrations must take into account the existence of a whole spectrum of frequencies. In this spectrum there must exist frequencies the wave-length of which is much greater than the lattice spacing, and a maximum frequency the wave-length of which is twice the lattice spacing. Owing to the very large number of frequencies (some 18×10^{23} per gram atom) distributed in the vibrational spectrum, some method of approximation must be devised in calculating their contribution to the vibrational energy. A successful approximation was proposed by Debye, who replaced the spectrum of a real crystal by the more easily calculated spectrum of a continuum. The only reference to a discrete lattice structure was introduced by breaking off the spectrum of the continuum at a maximum frequency ν_M. Debye's expression for the vibrational energy of a crystal

$$E = 9RT\left(\frac{T}{\theta}\right)^3 \int_0^{\theta/T} \frac{x^3dx}{(e^x-1)}, \text{ where } \theta = \frac{h\nu_M}{k},$$

bears about the same relation to experiment as van der Waals' expression does to actual deviations from the perfect gas equation.

The spectrum of real crystals differs from that of Debye's continuum both in showing a wave velocity decreasing with rise in frequency, in place of the constant value assumed for a continuum, and in showing a preferential distribution of frequencies around certain values, in place of the smooth distribution for a continuum. Formulæ have been proposed for the vibrational energy of crystals, involving more than one θ parameter, but since empirical equations automatically gain in flexibility by increasing the number of adjustable parameters, it is not yet possible to assess their theoretical importance[8] in detail.

One disadvantage of specific heat measurements, as a clue to the thermal vibrations of atoms in crystals, is the very fact that a whole series of measurements can be summed in terms of only one parameter—the characteristic temperature θ—which can be related to crystal structure. In principle, much more direct information about the 'mode of motion' of the atoms is obtainable from measurements of the decreased intensity of X-ray reflections with rise in temperature. The intensity of reflection I_T at temperature T from crystal planes with lattice spacing d is given by the expression

$$I_T = I_0 e^{-M},$$

where $M = 4\pi^2 \bar{u}^2/d^2$, I_0 is the intensity at 0° K., and $\bar{u}^2$ is the mean square displacement of the atoms normal to the crystal plane, due to thermal motion. The effect can be demonstrated by a simple model, and has been used in studying thermal vibrations in ionic and metal lattices[9]. It also indicates the zero point motion of atoms in a lattice at 0° K.

The heat motions of the atoms lead not only to a decrease in the intensity of X-ray reflections, but in addition to thermal expansion of the lattice. This is due to the atoms vibrating in a field the law of force of which is non-harmonic. A simple expression relating the coefficient of thermal expansion α with the specific heat C_v, the volume V_0 and the compressibility X_0, is

$$(\alpha V_0)/(C_v X_0) = -d \log \nu_M / d \log V.$$

For most crystal lattices, the maximum frequency ν_M decreases as the volume V increases, and in this case the lattice *expands* with rise in temperature. A correlation of thermal expansion with crystal structure is as yet limited to isolated cases[10].

In crystals containing hydrogen, a special method of studying lattice vibrations involves the replacement of hydrogen by deuterium. This leads to expansions of the lattice in certain cases, and the interpretation is simplified owing to the localization of the change at specific bonds in the crystal[11].

A limited number of crystals have other means of acquiring thermal energy, in addition to vibrations of the lattice. As a rule, these are detected by accurate specific heat determinations. The main features of accurate calorimetry can be summarized under the headings of accurate control of the supply of heat (usually by electrical means), accurate measurement of the rise in temperature of the substance (usually with a resistance thermometer or thermocouple) and accurate control of the heat exchange with the surroundings, obtained by suspending the calorimeter in a high vacuum, and surrounding it with an 'adiabatic' mantle maintained approximately at the temperature of the calorimeter.

When other means of acquiring thermal energy are present in the crystal, they show up on the specific heat curve by a 'hump', that is, a sharp rise in specific heat above the normal vibrational value, followed by an even steeper fall. Other properties of the crystals, such as the magnetic susceptibility, the dielectric constant, and the refractive index may vary rapidly over the same region of temperatures as the specific heat anomaly, and can be used as additional means of studying the phenomena, or for demonstration in a lecture.

Typical examples are the transformation in nickel (ferromagnetic-paramagnetic), the change from ordered to disordered alloy in β-brass, and the (presumed) rotation of methane and other hydrocarbons in their crystal lattices above a certain temperature, though many other cases are known. The almost catastrophic intake of thermal energy in all these cases is due to a co-operative effect between neighbouring molecules, which may be illustrated by reference to the rotation of methane. The crystal forces restraining rotation are due to the interaction of neighbouring molecules, which maintain preferred orientations in the lattice at sufficiently low temperatures. The thermal energy required by isolated molecules to overcome these restraining forces, and to rotate freely, may be quite large, but once they are rotating their restraint on their neighbours is lessened. Further molecules will thus have to acquire less thermal energy in order to rotate freely; the transition to complete rotation has analogies with an autocatalytic process[12]. This explanation is substantiated by experiments on the specific heat anomaly of methane with increasing amounts of krypton in solid solution[13]. The krypton atoms lessen the mutual restraint of neighbouring methane molecules, acting as lubricants, with the result that the abnormal intake of heat becomes less and less catastrophic.

The problems and results of calorimetry are of importance both for theories of crystal structure, and also in the calculation of equilibrium constants. The entropy of a solid can be written

$$S = S_0 + \int C_p \, dT/T,$$

and for a perfect gas, $S = S_0' + \int C_p \, dT/T - R \log_e P$, where S_0, S_0' are the (arbitrary) entropy constants. In order to calculate equilibrium constants solely from heats of reaction and specific heats, that is, from calorimetric measurements, it is necessary to evaluate these entropy constants. The solution proposed by the Nernst heat theorem can be stated in such a way that S_0 for solids is zero, so that S_0' for gases can be determined from the vapour pressure curve. Cases are known, however, where the assumption $S_0 = 0$ for the crystal does not agree with experiment. The simplest example arises in crystals of molecules such as NO, CO, N_2O, in which the molecules appear to have random orientations below the lowest temperature of measurement[14]. As a result, the experimental evaluation of the integral $S = \int C_p dT/T$ misses out a specific heat 'anomaly', merely because of the experimental difficulty in making measurements at still lower temperatures. The constant S_0 appears to be greater than zero, in compensation.

Interpretation of these and of other departures from the Nernst heat theorem is greatly facilitated by a knowledge of the crystal structures, and presents one more illustration of the interdependence of thermodynamics and theories of the structure of matter.

OBITUARIES

Sir Charles Hagbert Wright

SIR CHARLES HAGBERT WRIGHT, who died on March 7 last at seventy-seven years of age, was a notable librarian, a man of letters and a characteristic London figure. He was a man of strong personality tempered with kindness. To describe him as a born librarian may be thought to do him less than justice. He possessed that logic of mind, energy of character, organizing ability and power of handling men which are as necessary to the librarian of a great library as to the man of business. To these qualities he added a wide knowledge of languages and a love of literature.

Sir Charles's association with the London Library began some forty-six years ago, when the library was much smaller than it is to-day. His wide circle of friends enabled him to acquire valuable donations of books and to collect necessary funds for new buildings in 1896 and for subsequent extensions. He realized the essential part a large library has to play in the advancement of learning and was successful in inculcating in his staff the feeling that they too were concerned in this work.

From such a library as the London Library long arms stretch out, embracing the globe and gathering continually material for the enrichment of its stores of information. In his extensive travels Sir Charles made and improved such contacts, without which no great library can function effectually. Nor does a sometimes insufficiently appreciative public always realize that the services rendered by such a library depend on the smooth running of a train of mechanism comprising many wheels. I well remember with what interest Sir Charles explained to me, many years ago, the details of the hidden silent machinery in the London Library, much of which he had himself designed.

Russian subjects claimed the first place in Sir Charles's literary interests. Yet his book "Nicholas

Fabri de Peiresc", published in 1926, came within the field of science. As he said, "Here we have the phenomenon of an antiquarian who was equally engrossed in medicine and surgery, in astronomy and scientific research". The combination of naturalist and antiquary in his uncle, Edward P. Wright, may have given him a lead in that direction. Through his brother, Sir Almroth Wright, the celebrated pathologist, Sir Charles had many contacts with the scientific world, and he always endeavoured that the committee of the London Library should include scientific men. Alfred Russel Wallace and Sir Archibald Geikie were among the well-known men of science who served in this capacity in his time.

Although the London Library is essentially a library of general scope, its extent implies that it should contain valuable collections of scientific works. Sir Charles endeavoured especially to secure whatever he thought would be of value to future historians of science, and the Library's extensive representation in the history of science and of medicine is of special value to scientific men. S. C. BRADFORD.

Prof. S. Lees

PROF. SAMUEL LEES held the Chance chair of mechanical engineering at the University of Birmingham from October 1, 1931, until his death on January 27 last. The son of Alderman S. H. Lees, of Salford, he was born in that town on August 26, 1885. He received his early engineering training at Ferranti, Ltd., of Hollinwood and Charles Churchill and Co., Ltd. (afterwards The Churchill Machine Tool Co. Ltd.), of Broadheath, Manchester. Whilst a student of the Manchester School of Technology he gained a Whitworth Exhibition in 1905 and a Whitworth Scholarship in 1906. At about this time he won a prize of £200, open to technical students generally of Great Britain, offered by Messrs. George Newnes, Ltd., in connexion with their periodical *Technics*.

After proceeding to Cambridge he took his B.A. in 1909, and later his M.A. He was awarded the Rayleigh and John Winbolt Prizes in 1911, became Hutchinson Student, and was elected in 1912 a fellow of St. John's College. In 1913 he was appointed reader in applied thermodynamics in the Faculty of Technology of the University of Manchester.

From 1915 until 1918 Lees was with the Navy, first as engineer lieutenant and afterwards engineer lieutenant commander. Most of his war service was spent on research work at Portsmouth Dockyard and concluded with a short spell at Farnborough. After the War he returned to Manchester. From 1919 until 1929 he was Hopkinson lecturer in thermodynamics at the University of Cambridge, and for a number of years director of engineering studies at St. John's College. He left Cambridge to become consultant mechanical engineer to Silica Gel, Ltd., and spent some time in Baltimore, U.S.A., on problems concerning the application of silica-gel to industrial uses.

After two years in industry, Lees returned to academic life to take the chair at Birmingham. Here he reorganized the research work of the Department of Mechanical Engineering and was engaged in the investigation of several problems having a bearing upon air-conditioning and upon internal combustion engine theory and practice. These included the air-cooling of metal surfaces, heat transmission through metals and loose aggregates, the study of delay-period phenomena in compression ignition engines, catalytic and other methods of improving combustion in engines of this type, exhaust noise in internal combustion engines, electrical methods of indicating high-speed engines and the flow of gases through orifices and nozzles with the view of correlating experimental work with dimensional theory. Some of these researches were in an incomplete but advanced state at the time of his death.

Prof. Lees was a man of unassuming disposition and incapable of self-advertisement. A first-class teacher, a profound thinker on his subjects, helpful to the point of self-sacrifice to all with whom he was associated, his early death at the age of fifty-four years is a severe blow to the University of Birmingham and to his colleagues, his staff and his students, especially foreign students, who had an affectionate regard for him. He leaves a widow and two sons.

WE regret to announce the following deaths:

Prof. Alfred Bielschowsky, at Hanover, New Hampshire, U.S.A., for many years professor of ophthalmology at Marsburg and Breslau, and a leading authority on motor disturbances of the eye and the physiology and pathology of space sense, aged sixty-seven years.

Prof. Edouard Branly, the pioneer in radio communication, on March 25, aged ninety-five years.

Mr. E. T. Cottingham, the well-known maker of scientific time-recorders, on March 20, aged seventy years.

Sir Patrick Laidlaw, F.R.S., pathologist to the Medical Research Council, deputy director of the National Institute for Medical Research, on March 20, aged fifty-eight years.

Mr. W. H. Lovegrove, formerly conservator of forests, Kashmir, on January 25, aged seventy-two years.

Prof. E. Mapother, professor of clinical psychiatry in the University of London, formerly medical superintendent of Maudsley Hospital, on March 20, aged fifty-eight years.

Prof. D. S. Margoliouth, F.B.A., Laudian professor of Arabic in the University of Oxford during 1889–1937, on March 22, aged eighty-one years.

Prof. W. S. Miller, emeritus professor of anatomy in the University of Wisconsin, on December 26, aged eighty-one years.

Prof. Michael Siedlecki, professor of zoology in the University of Cracow.

Dr. Werner Spolteholz, emeritus professor of anatomy in the University of Leipzig, on January 12, aged seventy-nine years.

SHORT REVIEWS

ANTHROPOLOGY OF ARCHAEOLOGY

Aboriginal Woman, Sacred and Profane

By Dr. Phyllis M. Kaberry. Pp. xxxii+294+8 plates. (London: George Routledge & Sons, Ltd., 1939.) 15*s*. net.

DR. KABERRY'S observations among the aborigines of north-west Australia, of which certain of the results are given in this volume, mark a new departure in the study of the primitive peoples of that continent. While it is no new thing for women to enter the field of anthropological investigation with the specific object of illuminating the sphere of the woman among backward people—that is a matter of the anthropological history of more than a generation—and Australian records include the names of more than one notable woman observer, Dr. Kaberry has approached the problem of the tribal woman from what in Australia is a new point of view. Hitherto, both in form and content, tribal life and organization have been assumed tacitly to be mainly the province of the male members of the group, with the female as an appendage or adjunct of the male, performing, it is true, certain functions essential to the continuance of the group and to the life of the individual, but otherwise of little significance. Here in Dr. Kaberry's detailed record of the results of observations carried out among various tribes in 1934 and 1935–36 is set out the evidence of how far the female members can be regarded as socially individuals, and how far the functions attributable to them pass beyond the 'profane' in tribal life and enter into the 'sacred' province, in which the male has hitherto monopolized the centre of the picture in anthropological investigation.

If it be said that the results of Dr. Kaberry's investigations enlarge considerably the conception of woman's status and function in the Australian tribe, that need be no matter for surprise, at least for many who have regarded previous records from this aspect with some reserve. She has, however, gone considerably beyond most of her predecessors by transcending the form of tribal institutions and extending her inquiry to 'cases'—in other words, by finding out how far these institutions work, how far they are elastic, so as to admit alternative modes of behaviour, and how far they are flouted by the conduct of individuals. As a result, the aboriginal woman emerges not merely as an anthropological specimen, but also as a human being and an individual—essentially of the feminine order.

Herbert Spencer Betrayed

With some account of the repudiation of the "Descriptive Sociology" by his Trustees. By Alfred W. Tillett. Pp. x+68. (London: P. S. King & Son, Ltd., 1939.) 4*s*. 6*d*. net.

MR. TILLETT vigorously attacks the trustees of Herbert Spencer's will on the grounds: (1) that while the terms of the will required his estate to be applied to completing the publication of "Descriptive Sociology", which was uncompleted on Spencer's death, they acted *ultra vires* in publishing Dr. Rumney's "Herbert Spencer, Sociologist", in which Spencer as philosopher and man is vilified; and (2) that they determined the Trust and distributed the balance of the fund among the residuary legatees before the work, for which the trust was created, had been completed.

Mr. Tillett, though advised to the contrary, still hopes that it will be possible to obtain a judicial pronouncement on the position he has taken up; and it is therefore undesirable to express any opinion here, even if the case were not one involving difficulties of interpretation, legal and other. There is no doubt that in such matters open accusation is better than underground insinuation. It may be pointed out, however, that the trustees had exercised every care in becoming discharged of their trust. Not only had the Court already varied the terms of the will to meet changed conditions, but also the opinion of the Attorney General was sought before the trustees took final action. With the legal position of the trustees thus clarified, in view of recent development in sociological studies, further expenditure in this direction seemed to be largely waste.

BIOLOGY

Keys to the Phyla of Organisms, including Keys to the Orders of the Plant Kingdom

By Fred A. Barkley. Pp. iv + 40. (Missoula, Montana: Associated Student's Store, 1939.) 75 cents.

IN this pamphlet of thirty-nine pages, Dr. Barkley gives a series of dichotomous keys referring chiefly to the orders of the various 'plant' phyla. The keys have been drawn up to meet the needs of the author's class in plant morphology and have been so constructed as to reflect in large part the views of outstanding authors regarding certain groups. They are intended to give also a more or less comparative treatment of the ordinal category under the various phyla.

Students who have a general knowledge of systematic botany and zoology will find it useful first to get a bird's-eye view of the classification employed by referring to the outline given on pp. 26–27. In this outline the sequence of phyla, classes and orders follows that of the keys, and only in broad outline, therefore, can the classification be regarded as an expression of relationships. Organisms as a whole are divided into four kingdoms: Monera, Protista, Phyta and Zooea. Cohn's old group 'Schizophyta' is retained as a division of the Monera and serves to include Cyanophyceæ, Spirochætæ and Schizomycetes. An unusually wide interpretation is given to the Protista, since this kingdom is made to include not only Protozoa and Parazoa but also all the organisms commonly classed as Algæ and Fungi. Bryophytes head the list of the phyla placed in the kingdom Phyta and are followed in turn by Pteridophytes and Spermatophytes, the last phylum of which—the Anthophyta—includes the large number of orders into which Dicotyledons and Monocotyledons are divided. Apart from an occasional change of name and a different sequence, the orders of flowering plants are the same as those proposed by Hutchinson in "The Families of Flowering Plants". In the keys to the orders a great deal of detailed observation is compressed, much of which will not prove easy reading to the elementary student, but the inclusion of a useful glossary (pp. 29–38) will help to get over the difficulty. J. R. M.

Bibliography of the Larvæ of Decapod Crustacea

By Dr. Robert Gurney. (Ray Society, Vol. 125, for the Year 1937.) Pp. vii + 123. (London: Bernard Quaritch, Ltd., 1939.) 12*s*. 6*d*.

THE preparation of bibliographies is often a thankless task, although few would deny their importance. The present example covers the literature of the larvæ of Decapod Crustacea (excluding the Euphausiacea) up to May 1939. It comprises three sections—an alphabetical list of authors, a classified catalogue in which the literature is arranged zoologically, and an index to genera. Some eight hundred titles are recorded.

We have tested the work here and there both as regards completeness and accuracy, and have little criticism to offer. Every bibliographer knows that completeness is unattainable and even accuracy is curiously difficult to achieve. Nevertheless, we have noted only the following errors and omissions: the paper by Audouin and M. Edwards, 1828, on the nervous system of Phyllosoma, Dalyell's "Powers of the Creator", vol. 1, 1851, containing observations on Decapod larvæ, Leach's earlier article on Megalopa of 1814, and Leeuwenhoek's letters of 1686 and 1700 on the development of Crangon are omitted. Crawford and Smidt's paper on Panulirus should be dated 1922 and for "Larvæ, p. 9" read "Larva, p. 309"; Milne Edwards is not a hyphenated name and should be catalogued under Edwards; Hornell's papers on Squilla and Scyllarus were reprinted in a volume of "Microscopical Studies" in 1901; the reference to Linnæus should be to the twelfth edition, Holmiæ, 1767; and Slabber's figure of the zoea larva should be dated 1769.

Dr. Gurney is to be congratulated on the completion of a valuable piece of bibliographical research and the Ray Society for having undertaken its publication. F. J. C.

Basic Methods for Experiments on Eggs of Marine Animals

By Ernest Everett Just. Pp. x + 89. (London: The Technical Press, Ltd., 1939.) 6*s*. net.

THE methods used in experimental investigations of the eggs and spermatozoa of marine invertebrates depend very strongly on the adherence to some general rules. Some of these are set out in this little volume, which should be useful for beginners in the field of experimental embryology, and for the specialist whose work demands individual extension of methods. Whilst the techniques described apply to the gametes of American marine species, they are sufficiently general to be applicable also to the gametes of the same species, and to those of closely related species, in European waters. Dr. Just has developed his methods over a period of twenty-five years, so that the issue of this book was to be expected as a necessary supplement to his recently issued "Biology of the Cell Surface". In no wise can it be claimed to be a catalogue of all methods in use, but, nevertheless, the methods described, and especially those relating to preparations of fixed tissues, should be of value to cytologists.

Notes on the Genus Dioscorea in the Belgian Congo

By I. H. Burkill. (Extrait du *Bulletin du Jardin botanique de l'Etat*, Vol. 15.) Pp. 48. (Bruxelles: Jardin botanique de l'Etat, 1939.)

THIS important study is by one of the authors of the revision of the Eastern Dioscoreas. It will prove invaluable in compiling any general account of the genus in Africa. Twenty-three species are recorded with several varieties for some of them; two of the species are here described for the first time. These species of the Congo are attributed to six sections of which four twist to the left. A definition of each section is given, and a key to the species is provided for each plurispecific section. A full history and synonymy of every species will be found, together with a comprehensive statement of the known collectors and its distribution within and without the Belgian Congo. Many interesting notes are furnished on the depth below ground-level at which the tubers are seated, on their edibility and method of preparation for food; poisonous properties; bulbil production and self-protective measures. Of peculiar interest and value are the discussions on the origin, evolution and "ennoblement" (improvement and refinement by selective cultivation) of the most-prized yams. It is indicated that some of the problems involved can only be solved in the field and that "the paper is intended to direct all who are able to study the Congo Dioscoreas alive to points worthy of their particular attention".

A debt of gratitude is due to Mr. Burkill for collating much valuable information from many sources and adding the results of his own patient and extensive research, both in the herbarium and in the field, which has cleared up several obscurities.

CHEMISTRY

Perkin and Kipping's Organic Chemistry

By Prof. F. Stanley Kipping and Dr. F. Barry Kipping. Part 3. Revised edition. Pp. viii+615–1030. (London and Edinburgh: W. & R. Chambers, Ltd., 1939.) 9*s*.

OF late years there has been a marked dearth of works dealing with advanced organic chemistry in a manner suitable for students reading for an honours degree in chemistry. Part 3 of "Perkin and Kipping's Organic Chemistry" can be recommended with confidence to such students and also to research workers. It is a handy volume comprising some four hundred pages and yet not too bulky for an ordinary pocket. Its twenty-three chapters afford concise and up-to-date treatments of a surprisingly large number of subjects of current importance in organic chemistry, including physical properties, isomerism (four chapters) and isomeric change, carbohydrates (two chapters), terpenes and related groups (three chapters), carotenoids, anthocyanins, metallic ketyls, aromatic substitution, etc. The chapter on heterocyclic compounds (12 pp.) is limited to azoles, diazines and vitamin B. In this new edition the configurational formulæ of the sugars (which gave rise to difficulties as expressed in the first edition) have been revised, and two new chapters have been added: one of these deals with the theory of resonance (12 pp.) and the other with sterols, bile acids and other steroids (21 pp.). The text and formulæ are neatly printed, and there is a good index.

A Text-Book of Quantitative Inorganic Analysis

Theory and Practice. By Dr. Arthur I. Vogel. Pp. xix+856. (London, New York and Toronto: Longmans, Green & Co., Ltd., 1939.) 18*s*.

AS would be expected of a teacher with wide experience of students of all grades, Dr. Vogel has produced in this book a notable contribution to chemical literature and a valuable guide to those engaged in chemical study.

The book is divided into six chapters dealing respectively with the theoretical basis of quantitative analysis, the experimental technique required, volumetric, gravimetric, colorimetric and gas analyses. In each of these chapters, the reader will discover a wealth of detail not only of the more classical methods of analysis but also of the most up-to-date modifications and discoveries. Most of the new methods have been tried out in the author's own laboratory. In addition, there is a comprehensive appendix containing chemical data which will be of great value to practising analytical chemists, whilst teachers of chemistry will find much interest in the suggested schemes of study for various examinations.

Dr. Vogel's book can be confidently recommended to students of all grades as a sound, up-to-date and accurate treatise on methods of analysis, a study of which will be amply sufficient for all examinations up to the honours degree. The book should also be on the bookshelf of all industrial analytical chemists, who will find it a useful reference book in modern methods of analysis.

Physikalische Methoden der analytischen Chemie

Herausgegeben von W. Bottger. Teil 3: Chromatographie, Verdampfungsanalyse, Spektroskopie, Konduktometrie, Photoelektrometrie, Polarographie, Potentiometrie. Pp. xx+836. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1939.) 65 gold marks.

THIS book is more than merely a description of the application of a number of physical methods to analytical chemistry. This is due to the fact that the editors have taken a very broad view of what constitutes analytical chemistry. The consequence is that much pure physical chemistry finds its way into the volume. There is, of course, emphasis on experimental technique.

The main subjects treated are chromatographic analysis, analysis by fractional evaporation, spectroscopic analysis, photometric methods and analysis by conductometric, polarographic and potentiometric methods. It is absolutely impossible in a short review even to give a list of the contents, for they are so varied. The aim of each contributor is not only to describe methods but also to give enough practical details so that the reader may conduct the experiments with success. Moreover, each section of the book is copiously provided with references to recent literature. For example, the section on potentiometric methods includes at least one thousand references.

There is much in this book to interest physical chemists as well as those who wish to find the most useful analytical technique for any given problem. The index and table of contents make the search among such a mass of material an easy business. The volume is well printed and bound but is rather expensive.

H. W. M.

ENGINEERING

Electricity Meters and Meter Testing

By G. W. Stubbings. (Monographs on Electrical Engineering, Vol. 6.) Pp. x+216. (London: Chapman & Hall, Ltd., 1939.) 12*s*. 6*d*. net.

IT is only of recent years that the question of the metering of electric supply has been seriously tackled. The question itself is a most difficult one, and the introduction of tariffs and the theory of statistics, and attempting an impossible accuracy, have certainly not made it easier. The easiest way is to put a sub-standard wattmeter in series with the consumer's meter for a day or a fortnight and then read them both simultaneously. If they both read the same then everyone is satisfied. But the meter reader who has had his own sub-standard meter tested at a standardizing institution and knows the curve of error of his own meter sometimes wonders whether it is correct or not. The present limits for consumers' meters as described in the Electricity Supply (Meters) Act of 1936 are 2½ per cent plus or 3½ per cent minus. That is, the permissible error when the meter is going fast is less than when it is going slow. The test of the meter at no load should always be taken, and if it is rotating then it is a long and costly business to find out what is wrong.

From what we have said it will be seen that it is no easy matter to meter an electric supply. Even the expert who is thoroughly familiar with the apparatus used in an electrical laboratory, or even in a meter-testing house, will find that there are numerous problems inseparable from the everyday work of the meter-tester that are not yet satisfactorily solved. For example, there are errors due to bearing friction, fluid friction, frequency, phase, self-braking, temperature, varying load, voltage variation, wave distortion, official limits, tariffs, etc. It is no easy task to keep in good working order hundreds of thousands of little meters, and the task of the superintendent of a meter-testing department is no sinecure.

The author of this book has a thorough knowledge of the difficulties in the way in Great Britain and knows well the difficulties in many cases of treating equitably suppliers and consumers. He includes an appendix giving the titles of many recent books on the subject and also of technical papers. The reader will find that it is no easy matter to become a meter expert.

Elements of Practical Aerodynamics

By Prof. Bradley Jones. Second edition. Pp. viii+436. (New York: John Wiley and Sons, Inc.; London: Chapman & Hall, Ltd., 1939.) 18*s*. 6*d*. net.

THIS is the second edition of an American book, the first of which was reviewed in NATURE of July 31, 1937. It is an exceedingly lucid and simply written students' text-book, that should prove useful to engineers or physicists commencing the study of aeronautics. A feature of the book is the large number of worked examples in the text, and further exercises at the end of each chapter. These are carefully graded and form an admirable addition to the book; one which might well be added to most English books on this subject of the same standard.

The subject-matter has been brought up to date, and most of the more modern developments mentioned in a general way. Some of this later work is superficial, but not unduly so remembering that it is an elementary and necessarily restricted work. Among these are discussions on tapered monoplane wings, methods of working out low drag contours, performance calculations including approximate rapid prediction methods, problems of control and stability from the practical but not the mathematical point of view, and details of the more modern aerofoils (those more popular in the United States). A chapter on "Auxiliary Lift Devices"—about three pages—is disappointing, and makes no attempt to explain the many variations of the allied problems of speed range and control that arise from the use of these. Worked examples, as in some of the other chapters, would have been particularly valuable here.

As in the first edition, the book ends with chapters on such subjects as materials, meteorology, instruments, etc. These are accurate so far as they go; but are so short as to be of little use. They are illogical in a book with this title, and it seems a pity that the author did not confine himself to aerodynamics, and give fuller discussions upon the aspects of this in the relevant chapters.

FORESTRY

Principles of Forest Entomology

By Prof. Samuel Alexander Graham. (McGraw-Hill Publications in the Zoological Sciences.) Second edition. Pp. xvi+410. (New York and London: McGraw-Hill Book Co., Inc., 1939.) 24*s*.

WE welcome the appearance, after a decade, of a second edition of this well-known handbook. Considerable advances have been made in that period as regards our knowledge of the principles of forest entomology. The European pine sawfly, for example, has become prominent as a forest pest in that short period. Certain chapters of the book have been almost wholly rewritten: others have been revised, and the bibliography has been brought up to date.

Elementary Forest Mensuration

By M. R. K. Jerram; with a Chapter on The Measurement of Forests, by R. Bourne. Pp. x+124. (London: Thomas Murby & Co., 1939.) 8*s*. 6*d*. net.

IN this little book, Mr. M. R. K. Jerram states that the word 'elementary' has been prefixed to the title as the work is intended chiefly for the professional forester rather than research specialist, and he has been guided in his method of treatment of the subject by this factor. For the greater number of professional foresters, either in being or still in the student stage, forest mensuration is a practical part of their work—the higher branches of the subject are required by the research worker alone.

Still, the author gives an account of a few of the less well-known methods in use by research workers. Otherwise in his treatment of the subject Mr. Jerram deviates but slightly from the ordinary lines, which are not capable of much variation. An interesting chapter on "The Measurement of Forests" is contributed by Mr. R. Bourne, late lecturer in forestry at Oxford University. The book may be recommended as a useful text-book.

GEOLOGY

Geology of London and South-East England

By G. M. Davies. Pp. viii + 198 + 4 plates. (London: Thomas Murby & Co., 1939). 7*s.* 6*d.* net.

IN a recent broadcast on "Science in Wartime", Sir Albert Seward, then president of the British Association, commended to his listeners the interest and satisfaction that are to be gained from dipping into the history of past ages on the earth, and he chose as one of his examples the study of the London Clay. For those who, for cultural or utilitarian ends, would like to follow up this suggestion in the still rather heavily populated area of south-eastern England (and are prepared to take the risk of being arrested as spies in the course of their field studies), the book under notice appears at the opportune moment.

Instead of adopting the usual historical method of treatment—from ancient to modern—the author reverses the process in the belief that people will find it easier to work back from the known present to the unknown past. His treatment therefore opens with "made ground" and recent deposits, and passes on to the records of early man, ancient river deposits, the relics of the Ice Age, and so to the Tertiary rocks of the London and Hampshire Basins, the Chalk, and finally the pre-Chalk formations that are included within the area from the Fens to Oxford.

Other interesting subjects treated in a simple way are the Palæozoic floor under the east of England, the water-supply, the building-stones of London, and the development of scenery. Abundant photographs, text-figures of characteristic fossils, geological sections, sketch-maps and judiciously selected references to relevant publications (for those who wish to pursue the subject further) enhance the usefulness of the book.

Die Entwicklung der Kontinente und ihrer Lebewelt

Ein Beitrag zur vergleichenden Erdgeschichte. Von Prof. Dr. Theodor Arldt. Zweite, vollständig neubearbeitete und erweiterte Auflage. Band 1. Pp. xviii + 449–1005. (Berlin: Gebrüder Borntraeger, 1938.) 44 gold marks.

THE first edition of Prof. Arldt's great work appeared in 1907. Since that time, great advances have been made in palæogeography, biogeography and related sciences. Further, a complete new theory of the origin of continents and oceans has burst upon the geological world. This second edition is therefore a greatly expanded one, the first volume of it alone amounting to a thousand pages. The first part of this volume, issued in 1936, was noticed in NATURE of May 29, 1937, pp. 902–3. In it the question of the permanence of the earth's major features was raised, and the answer is not yet forthcoming even in the thousand pages of the present volume. It seems likely, however, that land-connexions between continental masses will be approved, but for the final answer we must await the second volume, which will contain the geological and cosmological findings.

In these thousand pages, then, we have a very detailed examination of the distribution of present and past life. So far as this colossal mass of information can be handled, it is summarized in a series of tables and charts. The last thirty pages of the volume deal with a few general topics, such as the geological distribution, the regions and the origin of life. By the ordinary geologist, who appreciates at least the quantity of the evidence produced by Arldt, the geological verdict will be awaited with interest.

MATHEMATICS AND ASTRONOMY

Modern Machine Calculation with the Facit Calculating Machine Model Lx

By H. Sabielny. Translated and revised by Dr. L. J. Comrie and Dr. H. O. Hartley. Pp. 74. (London: The Scientific Computing Service, Ltd., 1939.) 5*s.*

APART from the many excellent brochures issued by the leading makers of modern calculating machines, there is very little scientific literature on the subject. This is somewhat strange in view of the increasing use made of these machines in present-day business houses, coupled with the fact that probably the first adding machine was exhibited so early as 1884. The present manual will therefore be welcomed by all who wish to know something authentic about modern machine calculation. Mr. Sabielny's original text was published by Aktiebolaget Facit, Atvidaberg, Sweden, by whom the Scientific Computing Service, Ltd., under the direction of Dr. L. J. Comrie, was requested to prepare an edition suitable for use in English-speaking countries. Whilst the text deals particularly with the Facit Model Lx, much of it is applicable generally to other machines of similar type.

There are four parts dealing respectively with fundamental principles, examples of practical calculations, British currency and tables. The translators have followed the original text on the whole, although certain sections have had to be either cut out or modified. They have also incorporated some important new matter. Part 2, for example, on British currency, weights and measures, is new, whilst the very practical sections on 'short-cutting' in multiplication and division have been extended and a new method given for carrying out the rule of three with one operation without any embarrassment from complements.

The manual has been excellently prepared by the translators and should provide a very practical and scientific guide to the use of the modern calculating machine.

F. G. W. B.

(1) Annuaire pour l'an 1940

Publié par le Bureau des Longitudes. Avec des Notices scientifiques. Pp. viii+550+A16+B26+C54. (Paris: Gauthier-Villars, 1940.) 25 francs.

(2) The Observer's Handbook for 1940

(Thirty-second Year of Publication.) Pp. 80. (Toronto: Royal Astronomical Society of Canada, 1939.)

(1) AMONGST the various handbooks published each year mention may be made of the "Annuaire", published by the French Bureau of Longitudes, and "The Observer's Handbook" of the Royal Astronomical Society of Canada. The former has a long history, being first published in 1795, when it contained about eighty pages. The present comprehensive volume contains 550 pages besides an appendix. Its contents are grouped under the following headings: (1) Calendar for 1940 including astronomical data, tide predictions, etc.; (2) Earth—geodesy, meteorology, terrestrial magnetism, time determination; (3) Astronomy—star charts, minor planets, comets, stellar spectra, etc.; (4) Units of measurement; (5) Physical and chemical data. Two special articles are appended: "L'Espace Interstellaire", by M. Chas. Fabry (being the George Darwin Lecture of the Royal Astronomical Society for 1938), and "Le Bureau Internationale de l'Heure", by M. A. Lambert.

(2) "The Observer's Handbook" is purely an astronomical handbook intended more especially for the use of the non-professional. Besides providing a journal of astronomical events from day to day (datum, 75th meridian civil time), there are several useful tables. One of these gives the principal facts regarding 259 stars brighter than apparent magnitude 3·51. Another gives the position and type of the star clusters and nebulæ contained in Messier's catalogue compiled in 1781. A rough chart directs attention to the remarkable grouping of bright planets which occurred on February 28 (see also NATURE, January 27, p. 146). The transit of Mercury across the sun's disk on November 11–12 receives notice as it will be partly visible in Canada.

Structure of Algebras

By Prof. A. Adrian Albert. (American Mathematical Society, Colloquium Publications, Vol. 24.) Pp. xi+210. (New York: American Mathematical Society, 1939.) 4 dollars.

NOT only the contents, but even the title of this book may puzzle many good mathematicians of the older school. Algebra seemed to be a stereotyped subject which started with substitution, addition, subtraction, multiplication and division, had a great deal about equations, progressions, the binomial, exponential and logarithmic theorems, and then, after some chapters on miscellaneous topics, concluded with determinants and the theory of equations. There were a few pages headed the "Fundamental Laws of Algebra", which were generally felt to be an unnecessary statement of the obvious. At one time invariants came into fashion, and were spoken of as the "Modern Higher Algebra".

Now recently books have appeared having scarcely anything in common with older books except their titles. In Prof. Albert's "Modern Higher Algebra" (Cambridge University Press, 1938) the subjects dealt with are groups, rings, integral domains, fields and matrices. The subject of matrices, so important in quantum mechanics and factor analysis, is here taken as the starting point for the discussion of abstract entities satisfying the same laws as certain matrices. These entities are known as linear associative algebras. In the book under review a more advanced treatment of these algebras is given, including recent advances due to R. Brauer, H. Hasse, E. Noether, and the author himself.

MEDICAL SCIENCES

Bergey's Manual of Determinative Bacteriology

A Key for the Identification of Organisms of the Class Schizomycetes. By David H. Bergey, Robert S. Breed, E. G. D. Murray and A. Parker Hitchens. Fifth edition. Pp. xi+1032. (London: Baillière, Tindall & Cox, 1939.) 45*s*.

IN the sixteen years that have elapsed since the first publication of Bergey's "Manual" the work has undergone considerable change and amplification; many of the mistakes that detracted from the earlier editions have been rectified and the present edition, under its capable board of editors, shows a marked advance on its predecessors.

The assistance of experts has been made use of in the revision of certain groups—particularly in the realm of serology—and for the first time attention is directed to the serological grouping and typing of the hæmolytic streptococci and to the work of the Salmonella Sub-committee of the Nomenclature Committee of the International Association of Microbiologists on the taxonomy and classification of the genus *Salmonella*. In the latter connexion be it observed, however, that the organism of typhoid fever is still placed in the genus *Eberthella* instead of in the genus *Salmonella*, where by virtue of its serological characters it most certainly belongs, and that notwithstanding the serological identity of *Salmonella pullorum* and *Salmonella gallinarum* the latter is taken out of the genus *Salmonella* and placed in the genus *Shigella*, along with the dysentery bacteria. Furthermore, no mention is made of the significant serological relationship of the organism of tularæmia with the members of the genus *Brucella* and it is relegated to the genus *Pasteurella* on purely negative characters. The curious statement is made, moreover, that this widespread disease is only known in North America.

Strange omissions are still noticeable: one searches in vain for description of the organisms of pleuropneumonia and contagious agalactia and the other members of the group—this in spite of a considerable and growing literature on the subject. No doubt these and other questions will be considered at some future date and necessary action taken by the recently appointed Judicial Commission of the Nomenclature Committee of the I.A.M., of which the editor-in-chief of the "Manual" is one of the joint-secretaries.

William B. Wherry, Bacteriologist

By Martin Fischer. Pp. x+293. (Springfield, Ill., and Baltimore, Md.: Charles C. Thomas; London: Baillière, Tindall & Cox, 1938.) 27*s*.

THIS is in its way a quite unique biography of a bacteriologist, W. Buchanan Wherry (1875–1936), professor of bacteriology and hygiene in the Cincinnati College of Medicine, by an author, Prof. Martin H. Fischer, who was his subject's colleague and lifelong friend and has already earned for himself distinction in biographical literature. Though Wherry's services to bacteriology can scarcely be said to have been of an outstanding nature—perhaps his most important contributions were his recognition, practically simultaneously with McCoy, of bubonic plague among the ground squirrels of California and his isolation for the first time of *B. tularense* from a human case of tularæmia (Wherry and Lamb, 1914)—he had acquired in the course of his career as a bacteriologist in Manila, California and Mexico a very varied experience of tropical diseases and their methods of study.

Wherry must undoubtedly have had a great genius for friendship, and Fischer's tribute to his friend's life-work, based as it is on the numerous letters that passed between them since college days, and written in the very glowing terms employed by some American biographers of scientific men both living and dead, is sure to exert a powerful popular appeal. Perhaps the most interesting portions of the book are those that recount the life-story of Wherry's father, a missionary in India of strictest orthodoxy, and of his mother, sisters and brother. Letters that passed between the parents and the son—for they were all carefully preserved—throw a penetrating light on the daily doings of an Indian missionary and the financial struggles that seemed always to be pressing. For these revelations alone the book deserves a wide audience. It is beautifully produced—it represents in fact the last word in typography—and numerous excellent photographs relieve its 300 pages of text.

The Anaerobic Bacteria and their Activities in Nature and Disease

A Subject Bibliography. By Elizabeth McCoy and L. S. McClung. Vol. 1: Chronological Author Index. Pp. xxiii+295. Vol. 2: Subject Index. Pp. xi+602. (Berkeley, Calif.: University of California Press; London: Cambridge University Press, 1939.) 50*s*. net.

THE material assembled in these two volumes consists of an index to the bibliography of a subject which is unusually scattered. Spore-forming and non-spore-forming species of anaerobic bacteria have come under review and 10,500 original articles published up to the end of 1937 are cited. In vol. 1 is found a chronological list of all the references arranged alphabetically under the authors' names; complete cross-reference entries are included for each of the joint authors together with the full title of each paper, a task involving approximately 120,000 entries. Vol. 2 consists of a general subject index, the references again being listed chronologically under the author's names; in this volume, however, the title of the paper is not given but can be obtained by reference to vol. 1.

On first inspection the subject index outline appears adequate, but in practice the inherent difficulties of the system are all too quickly apparent. For example, if one desires to know the published work concerning the production of *Cl. welchii* antitoxin, one turns to vol. 2 and finds under the general heading of "Antitoxins" more than 400 entries on the general problem of antitoxin production for any of the anaerobes. Further, the absence from vol. 2 of the titles to papers compels one to refer for each entry to vol. 1; obviously an impracticable task. In the absence of a more clearly defined classification of both spore-forming and non-spore-forming species, it is difficult to see how the authors could have overcome this practical problem. If in future editions of this work vol. 1 was allowed to lapse and remained in the archives as a historian's guide, and the subject-matter of vol. 2 was expanded to include the title of papers the difficulty would, in part, be solved and our searchings simplified. The authors could not have hoped that the system of indexing they have adopted would be generally acceptable by all classes of workers, but they must be gratefully thanked by research workers and historians alike for undertaking the formidable task of collecting and collating such diffuse material.

Everyday Fare for Fitness

By Dr. Stanley B. Whitehead. Pp. 166. (London: John Lane, The Bodley Head, Ltd., 1939.) 5*s*. net.

THIS little book, of which the author is an advocate of meatless fare, is divided into two parts. The first deals with what he regards as the merits and demerits of everyday food from the point of view of fitness. Everyday meals which he considers suitable for the manual worker, brain worker and nervous type are described, and tables are included of body-building foods, energy-providing foods, heat-producing foods, and health-protective foods. The second part contains more than two hundred recipes under the headings of breakfast dishes, salads, savouries, roasts and entrées, soups and broths, egg dishes, sweets, puddings and health drinks among which alcohol finds no place.

PHYSICS

Rheology of Suspensions

A Study of Dilatancy and Thixotropy. By Hugo Levin Röder. Pp. xiv+86. (Amsterdam: H. J. Paris, 1939.)

DILATANCY (the Osborne-Reynolds phenomenon) has proved more difficult to measure quantitatively than has any other rheological anomaly, and the author's failure to obtain satisfactory data for dilatant systems with a modified Stormer viscometer is therefore not surprising.

Röder goes on to describe an apparatus in which a small sphere, rigidly attached to a car drawn on rails by means of a weight, is swept through the material to be investigated. The friction of this arrangement is considerable, but in the case of a true fluid there is satisfactory proportionality between the applied weight and the rate of shear if a constant friction term is subtracted from the weight. Aqueous pastes of quartz and rice starch give initially a rise in rate of shear as load is increased, but finally settle to a constant rate independent of further loading. In carbon tetrachloride, the same materials show a thixotropic, instead of a dilatant behaviour, and comparison is made with the thixotropic properties of paints. In dilatant systems, the material 'builds up' in front of the shearing body like snow against a snow-plough, a phenomenon similar to that described by Jordan as occurring in the straining of muscles. The thesis ends with a rather inadequate summary of selected books and papers on thixotropy and dilatancy.

Röder's work will be welcomed as making definite progress towards a solution of the important industrial problem of the measurement of dilatancy, but it is to be regretted that the author does not deal more adequately with earlier work, the thesis giving the impression of having been written somewhat hastily. G. W. S. B.

Décharge électrique dans les gaz

Par Prof. Marcel Laporte. (Collection Armand Colin, Section de physique, No. 216). Pp. 222. (Paris: Armand Colin, 1939.) 15 francs.

ELECTRIC discharge in gases is the subject of the new volume which Prof. Laporte has added to the useful series of monographs published by Armand Colin. It is remarkable how much information is contained in each of these small and inexpensive books; both the editor of the Physics Section, M. Ch. Fabry, and the author are to be congratulated on this addition to the collection. The first six chapters deal with the ionization of a gas in its various aspects, then come five chapters on various forms of discharge, and the last two are concerned with gas discharge tubes as sources of light, including white light. Honours students of physics would do well to study this book.

Theory of Heavy Quanta

Door Frederik Jozef Belinfante. Pp. xii+126. ('s-Gravenhage: Martinus Nijhoff, 1939.)

SINCE 1937, the evidence from the study of cosmic rays has increasingly pointed to the existence of a particle about a hundred times more massive than the electron, giving support to a suggestion of Yukawa's in 1935 that the forces binding protons and neutrons together in atomic nuclei might be connected with particles of about that mass. Since Yukawa's first paper, much theoretical work has been done and the subject has now reached a stage when a general survey is possible. Unluckily the new particle does not readily lend itself to direct laboratory investigation, and there are still many possible formulations of the theory, all of which have to be elaborated until further indirect comparison with experiment is possible.

It is therefore natural that this tract should deal mainly with mathematical methods and be more useful to the theoretical physicist than to the experimenter. Actually the latter will get even less from it than would have been possible had the material been more suitably presented. The exposition lacks conciseness, and the discussion of the practical conclusions from the theory suggests wide but ill-digested reading. The mathematical style is not elegant; too many symbols are introduced, and equations which could be written more concisely confusingly cover half a page in vector notation at a stage when this is unnecessary. At the present stage of the theory it is of course difficult to choose the best mathematical apparatus; the author advocates the use of "undors", which are expounded in a preliminary chapter.

PSYCHOLOGY

New Ways in Psychoanalysis

By Dr. Karen Horney. Pp. 313. (London: Kegan Paul & Co., Ltd., 1939.) 12*s*. 6*d*. net.

THIS book is an attempt to evaluate critically some of the main assumptions underlying the Freudian system. After a somewhat verbose discussion, the author arrives at the conclusion that most of these assumptions have to be discarded and others substituted in their stead.

The argument begins with the assertion that Freud was too much influenced by the mechanistic philosophy of the nineteenth century. His theories of fixation, regression, repetition-compulsion, and of the supreme importance of infantile experience are instanced as types of mechanistic rather than of dialectic thinking. According to Freud, present manifestations of neurotic behaviour are not merely conditioned by the past, they contain nothing but the past. The mechanistic biology of Freud's early days, according to which evolution was merely a redistribution of existing elements, found in his theories a psychological expression. Likewise, his tendency to view psychic processes as pairs of opposites appears to the author as an expression of the dualistic thinking prevalent in the last century, whilst his notion of behaviour as the direct derivative of instinctive patterns is regarded as without basis in fact.

The reader will welcome this critical approach to the subject. He will also welcome the new stress upon sociological and cultural influences in fashioning human behaviour, for he will find this in accord both with current experimental results in the field of conditioning and with the growing realization among social psychologists that the key to motivation is to be sought in the nature of the social environment rather than in innate patterns of conduct. That neurosis arises in particular as a result of the struggle to cope with a hostile competitive environment is perhaps the most interesting point raised in the book. This belief is based on the author's assumption that the dominant human need is for security—principally in the economic sphere.

Laboratory Investigations into Psychic Phenomena

By Hereward Carrington. Pp. 255+25 plates. (London: Rider & Co., n.d.) 15*s*. net.

THIS volume is a useful handbook for those psychical researchers who want to have by them a well-documented and fairly critical account of the attempts that have been made to bring so-called supernormal phenomena into the laboratory and to subject them to tests made by instruments of precision.

After a brief historical introduction the author continues by describing the results of his own experiments, which consisted for the most part of an investigation of the validity of the instrumental tests which had been devised in the past. It is in this section that we meet again with the rather pathetic attempts to demonstrate such alleged phenomena as special human radiations proceeding from hands or eyes; the effect of the will on material objects; or some sort of instrumental communication with the spirit world. In his experiments, designed to repeat the results claimed by earlier enthusiasts, Mr. Carrington met with but little success, and he points out how, in a number of cases, the previous results may have been due to mechanical defects in the apparatus employed, faulty procedure during the experiments, or more simply still to a false interpretation of the readings given by the various devices.

In trying to repeat many of these attempts Mr. Carrington has done a useful work, and the record here printed, even though largely negative (and indeed because of it), will be found to be a wholesome corrective to those who follow in the path of his predecessors, and again attempt to introduce dynamoscopes, magnetometers, sthenometers, volometers and the rest.

TECHNOLOGY

Photography, its Principles and Practice

A Manual of the Theory and Practice of Photography. By C. B. Neblette. Third edition. Pp. xi+590. (London: Chapman & Hall, Ltd., 1939.) 30*s*. net.

ALTHOUGH photography enters very largely into all branches of scientific research, many investigators have only the most rudimentary knowledge of the characteristics of the materials with which they work. No doubt much time and trouble might have been saved had that information been available at the time of experiment. This well-known book—now in its third edition—is just the kind of manual for a scientific worker who is not specially interested in the theory of photography, but who desires a proper scientific account of all the processes of photography in order that he may use the tool to the best possible advantage.

The volume deals with every phase of photography, beginning with the camera and its optical system, emulsions, latent image and sensitometry. The whole of processing to the finished print is given in detail. Even the less usual types of printing process are described in such a manner that they may be practised. Colour photography is dealt with, but in less detail. One very good feature of the book is the system of quoting references. The necessary references immediately relevant to the text are given, but in addition there is on nearly every page a series of references to general articles so that any given topic may be followed up in the photographic literature. 'Neblette' is therefore a useful addition to the library of anyone having to practise photography in a scientific laboratory. It is no less useful to the serious amateur photographer with a limited knowledge of chemistry and physics.

Theory and Design of Valve Oscillators

For Radio and other Frequencies. By Dr. H. A. Thomas. (Monographs on Electrical Engineering, Vol. 7.) Pp. xvii+270. (London: Chapman & Hall, Ltd., 1939.) 18*s*. net.

THE thermionic valve occupies a unique place in the field of communication engineering, in which its use in the generation of oscillations is a particularly important aspect.

The present monograph aims at bringing together all the important work which has been done on valve oscillators of the usual types. Particular attention is given to a detailed theoretical examination of the factors which affect the character of the oscillation. Here, then, one finds, after a preliminary survey of fundamental principles, chapters devoted to efficiency, wave-form and frequency of oscillator systems. In dealing with frequency, the treatment is very full. The frequency changes induced by time changes in the oscillatory circuit itself are given the importance they deserve in a scientific presentation of the subject. Finally, the question of frequency stability is surveyed in all its ramifications.

Dr. Thomas has presented his subject in a clear and ordered way. Due to his expert knowledge, he is able to lay bare the core of a problem with a conciseness that is admirable. This is a book which radio engineers, particularly those on the research side, will find really helpful. L. J.

A Handbook on Ventilation, including Air Conditioning

By Percy L. Marks. Pp. viii+138+1 plate. (London: The Technical Press, Ltd., 1938.) 7*s*. 6*d*. net.

THIS short treatise is not concerned with theories but confines itself to established facts and usage and, in some cases, expresses the views of consulting engineers and manufacturers recognized as experts. The author has adopted a discursive style and, after presenting the general considerations, goes on to describe the several methods employed in various circumstances and the fittings and material used. On the activities of dry rot some valuable information is given, and there is a chapter of ventilation suggestions for different classes of buildings which should prove useful. While the book does not go nearly far enough into detail to constitute an independent guide, it would make a valuable addition to a more formal text-book by reason of the numerous practical ideas it contains.

NEWS AND VIEWS

Sir Benjamin Baker, F.R.S. (1840–1907)

It is just fifty years ago this month since the famous Forth Bridge was opened and a hundred years ago since one of its designers, Sir Benjamin Baker, was born. The son of Benjamin Baker of Carlow, Ireland, Sir Benjamin was born in Somersetshire on March 31, 1840, and at the age of sixteen was apprenticed at the Neath Abbey Iron Works, South Wales. At the age of twenty he entered the employ of a civil engineer in London and two years later began his long association with Sir John Fowler (1817–98), who was then engaged on the construction of the first part of the London Underground Railway. Baker first gained recognition by a series of articles in *Engineering* in 1867 on "Long-Span Bridges". This series was followed by others on beams, brickwork and urban railways. In the 'seventies plans had been drawn up by Sir Thomas Bouch for a bridge over the Firth of Forth, but the failure of his Tay Bridge led to a reconsideration of the scheme.

In 1881 the railway companies interested requested their consulting engineers T. E. Harrison, W. H. Barlow and Fowler, with whom Baker collaborated, to report on the feasibility of a bridge over the Forth, and the type of bridge. The report recommended a cantilever bridge with a central supported girder, a type first adequately treated by Baker in his articles of 1867. The great work was begun in 1883 and completed in 1890, Baker then receiving the honour of knighthood. The second great work for which Baker will be remembered is the Aswan Dam on the River Nile, 6,400 ft. in length, carried out in the years 1898–1902 at a cost of £3,250,000. He was consulted regarding many projects both at home and abroad, acted as an arbitrator, and served on many commissions and committees. He was elected fellow of the Royal Society in 1890, and served as president of the Institution of Civil Engineers in 1895. He died unmarried on May 19, 1907, and was buried at the village of Idbury in the Cotswolds. Two years later a memorial window to him was erected in the north aisle of Westminster Abbey.

Substitutes for Imported Fuels

In the House of Commons, on March 20, Mr. Geoffrey Lloyd, Secretary for Mines, stated that Sir Harold Hartley had been appointed honorary adviser on the development of home-produced fuels. A number of leading representatives of industry, finance, and technical science, under the chairmanship of Sir William Bragg, had been asked to make a rapid survey of the subject in the light of war conditions, and within a month this authoritative body completed its survey. On its recommendations the following six specific problems are being investigated simultaneously: (1) the production of oil from coal by synthetic processes, under the chairmanship of Sir William Jowitt; (2) the products of low-temperature carbonization, under Lord Henley; (3) the liquid products of high-temperature carbonization, under Mr. Davidson Pratt; (4) alternative fuels for internal combustion engines, under Viscount Ridley; (5) the development of the use of colloidal fuel, under Mr. Irvine Geddes; and (6) the more efficient use of fuel generally, under Sir Clement Hindley.

A report has already been received, Mr. Lloyd said, on the recovery of benzole. This indicates that already additional crude benzole is being recovered at the estimated rate of 15,000,000 gallons a year, and that an extension of voluntary effort should secure a further 12,000,000 gallons a year. A survey has also been completed which shows how our production of tar, creosote, and pitch can take the place of imported fuel oil and bitumen to the extent of some 300,000 tons in the current year. Mr. Lloyd stated in conclusion that action already taken on the basis of reports received will result in obtaining in the current year some 32,000,000 gallons of substitutes for imported oil.

Economic Aspects of War

The economic aspects of war are ably discussed by Mr. G. Crowther in an Oxford Pamphlet on World Affairs (Oxford: Clarendon Press. 3*d.* net), entitled "The Sinews of War", in which he maintains that war is now an industrial proposition, being more influenced by the science of economics than by the art of strategy. The demand of war for the whole of a nation's industry and wealth has given an immense advantage to the rich country. Limiting himself to the question of men and materials, Mr. Crowther compares the resources of man-power and materials available to the Allies and to Germany. In almost every respect the Allies have an overwhelming advantage, and our advantage in man-power will increase the more Germany succeeds in making her raw materials at home. To win the War, however, even with these advantages, economic mobilization is essential. We must keep the seas open to our trade while closing them to the enemy; we must prevent the enemy from over-running our industrial areas or bombing them out of existence before they convert our advantages of man-power and materials into a military superiority. We must also preserve our ability to pay for imports by maintaining and increasing our export trades, and be prepared to reduce to the minimum the amount of man-power and materials consumed for purposes other than war. Finally, we must be energetic and speedy in organizing the transfer both of men and materials into their war-time jobs. In laying down programmes of war production, we must be content with nothing short of the maximum that is physically possible.

Tuberculosis and War

IN a recent paper on this subject (*Paris méd.*, 1, 52; 1940), Dr. E. Rist, of Paris, remarks that war favours the extension and aggravation of tuberculosis not only in belligerent nations but also in neutral countries, owing to the economic disturbance caused by the blockade, the scarcity of indispensable articles due to the destruction of merchant shipping and the hindrances of all kinds offered to the transport of goods by land and sea. During the War of 1914–18, the mortality curve from tuberculosis, which had fallen from 1900 to 1914, rose sharply from 1915 to 1918, and did not decline again until after the conclusion of peace. Among the numerous causes of an increase of endemic tuberculosis in war-time, one of the most serious is the rapid and wholesale evacuation of urban and rural populations to districts which are not sufficiently prepared to receive them, with the result that numerous healthy persons become infected with tuberculosis by those suffering from an active form of the disease.

Another factor leading to increase is the interruption of the most successful method of treatment of pulmonary tuberculosis, consisting in various forms of collapse therapy, especially artificial pneumothorax, caused by evacuation of patients to areas where there are no practitioners familiar with the technique. Other factors found to be responsible for the spread of tuberculosis are overwork, especially among those engaged in war industries of various kinds, under-feeding, as was illustrated in Denmark during 1914–18, and mental worry, the importance of which was emphasized by Laennec long ago. In conclusion, Dr. Rist, while admitting the necessity of an ample supply of tuberculosis experts in the armed forces, emphasizes the importance of restoring to civil practice a large number of them who are employed on quite unsuitable duties.

British Museum (Natural History)

LECTURE tours in the British Museum (Natural History) on Saturdays at 3 p.m., and on the first Sunday in each month at 3 p.m. have been arranged. London museums are re-opening their doors, and although many treasures have had to be moved away to safety from the Natural History Museum, their places have been filled to some extent by special exhibitions and new grouping. Two of the galleries are being used for a special exhibition to show Nature in the service of man. The exhibits illustrate the animals and plants from which our most important textiles are produced; sources of oil, animal, vegetable, and mineral, and some of the industries in which the various oils are needed; materials from which cosmetics and surgical requisites are prepared; the use made of spiders' webs and the origin of domestic breeds of poultry, cattle, pigs, etc. There is a section showing the animals particularly useful in war, such as white mice, canaries, reindeer, and Airedale dogs. Another gallery which has been proving a great attraction during the few weeks of limited opening is the Whale Hall, where a full-size model of a Blue Whale 92 feet long is on view—a treasure certainly, but much too large for evacuation!

Night-Shining Eyes

MOST people are familiar with the greenish gleam which shines from the eyes of a cat when a beam of light is directed upon them at night, and are aware that the glow can be seen only when the observer's line of vision is closely parallel with the beam of light. The phenomenon has been investigated in many animals by E. P. Walker, assistant director of the National Zoological Park of the Smithsonian Institution, and his results are referred to in the current Year Book of the Institution. The apparatus used in the tests was a reflecting head lamp, similar to a hand torch, worn on the forehead and connected with a three-cell battery in his pocket. The best results were obtained with a beam of moderate intensity, the effect of an intense beam being to make the glow less conspicuous or entirely to prevent its appearance. The shining is due to reflection from some surface in the eye, but its colour and character vary with the kind of animal. Colour ranges ran from silvery to blue-green, pale gold, reddish-gold, brown, amber and pink, and while most resembled reflection from a burnished metal surface, those of crocodiles and alligators gave the observer the impression of gazing into "a brilliantly glowing pinkish opening in a dull-surfaced bed of coal".

In the case of glowing eyes, the appearance is as if one looked through the pupil of the eye and saw reflection from the surface of the retina, but where the gleam was metallic in character there was no impression of looking into the interior of the eye. In the latter case, however, a difficulty arose because in most cases the reflection disappeared at a distance closer than from eight to twenty feet, so that the actual reflecting surface could not be determined. In some forty species of mammals and reptiles tests were made with red and blue coloured beams of light, but these made little change in the reflected gleam except to add a corresponding tinge of red or blue, a result which confirms the suggestion of simple reflection without any real animal light. To some degree there is a family resemblance in the character of the gleams, for most rodent eyes shine dully in brown, hazel or amber, although in porcupines the reflection is brilliantly silver. No shine was obtained from the eyes of higher apes or monkeys and no proof of the alleged shining of human eyes, yet, curiously enough, the most brilliant reflections of all were from the eyes of two of the lemurs, the slow loris and the potto.

Ethnological Reconnaissance in New Guinea

MUCH of the Mandated Territory of New Guinea is still uncontrolled, and even unexplored. Notwithstanding the difficulties of the country, the policy of exploration with a view to control is pursued with as little intermission as circumstances allow and has made substantial additions to knowledge in the information collected relating to the culture of previously unvisited or unknown peoples of the interior, notably in the regions adjacent to Mt.

Hagen. A recent report to Sir Walter McNicoll, administrator of the Mandated Territory, by Mr. J. L. Taylor, assistant district officer, records the results of a patrol carried out by him in unexplored country westward from Mt. Hagen to the border of Dutch New Guinea, and northward towards the southern tributaries of the Sepik River during March 9, 1938–June 19, 1939. The area surveyed consisted of some 20,000 square miles, and was found to be for the most part of temperate climate, such as might be suitable for European occupation. The future of the country traversed is said to lie in agriculture and pig-raising.

Large numbers of natives were encountered, most of whom appear to have been friendly, though on more than one occasion the patrol was attacked and suffered some casualties. Among natives to the north-west of Mt. Hagen, who had not previously seen a white man, the members of the patrol were regarded as spirits of the dead returned to earth. One of them, while taking observations from a tree, received the offering of a pig and was asked to ascend to heaven. In another village, the women were kept at a distance in the belief that they would die if they beheld these spirits. Among the more remarkable features in the culture of the peoples encountered, of which some particulars are given in a dispatch from the Canberra correspondent of *The Times* in the issue of March 26, is a system of deep drains or sunken roads, in the form of an elaborate complex of trenches, which serves both for defence and in cultivation as an effective drainage system, or as a protection against the ravages of pigs. Another remarkable culture trait is the use of wigs of human hair, made by professional wig-makers. Each man, it is said, aimed at having at least one wig made of his own hair. The tribes of the area were found to be keen traders, the most important and much sought after commodity being salt prepared from wood burnt after saturation in salt-springs.

Archæological Investigations in Jerusalem

Excavation of the remains of certain of the ancient walls of Jerusalem carried out by Mr. C. N. Johns on behalf of the Department of Antiquities has produced results of considerable archæological interest and historical importance. These results include the establishment of a chronological sequence in the remains of these ancient walls, which carries back to pre-Herodian times—certainly to the Maccabees and possibly even to the days of Nehemiah, although the evidence for the latter is archæologically undated. A further result is the confirmation of a tentative identification, made in the seventies of the last century, of the so-called Tower of David with Phasael, the third of the three towers described by Josephus as erected by Herod the Great. The systematic exploration of the site was made possible by the demolition of the Turkish barracks under the British occupation, and was undertaken by the Department of Antiquities in 1934 through the direct personal interest of Sir Arthur Wauchope, then High Commissioner.

The excavation, as described in a dispatch from the Jerusalem correspondent of *The Times* in the issue of March 23, has laid bare the old wall inside and parallel to the present north and west walls of the Citadel as reconstructed by the Crusaders and Mamelukes. This fragment of the old wall consists of three towers, Phasael and those named respectively by the excavators the Corner Tower and the South Tower, and their connecting curtain walls. The curtain between Phasael and the Corner Tower is of crude chalky stone solidly laid without mortar on the native rock scarp. Stratified remains of pottery suggest that this may go back to Jonathan Maccabæus; but in fact it incorporates an even earlier and clumsier wall, as previously mentioned, archæologically undated. The Maccabæan wall was partially demolished shortly after its erection, in a battle, presumably during the sieges by one or other of the Antiochus dynasty, of which the relics are seen in iron and bronze javelin heads and stone ballista balls. There is now evidence that after repairs it was reconstructed in the remarkable protective works of Herod, in which the tower Phasael was the strongest and most striking, rising from a cube of solid masonry, measuring 68 ft. on each side, in two stages to a height of 155 ft. In addition to their intrinsic interest, these discoveries will tend to throw light on other problems of the character and appearance of the Holy City at the opening of our era.

Trotula and the Ladies of Salerno

In a paper read before the Section of the History of Medicine of the Royal Society of Medicine on January 10, Dr. H. P. Bayon stated that several contemporary writers maintained that a fictitious Trottus was the author of "De passionibus mulierum", which was usually ascribed to Trotula of Salerno, a matron mentioned in the text of most manuscript copies and therefore a definite person. Whether she wrote or compiled the chapters "De ornatu mulierum" is not ascertained, but a study of early manuscript texts dealing with cosmetics seems to afford some clue. The gynæcological chapters are notable because of the recommendation of the support of the perinæum in childbirth and the primary suture of the perinæum. The many manuscript copies, printings and literary allusions concur in showing the appreciation which Trotula enjoyed during the twelfth to sixteenth centuries.

The references in the text of Trotula's work to Saracens, many drugs from the East, the avoidance of magical formulæ and hagiology, together with the description of alchemical manipulations, indicate the personal influence of Moslem and Hebrew physicians; in other Salernitan writings, quotations from the Old Testament are preferred. It is recorded that Costanza of Salerno lectured on medicine during the reign of Giovanna I of Anjou (1326–82); she was probably the first woman professor. The decline of the College of Salerno must have occurred after its destruction in the sack of the town in 1194. In academical teaching Salernitan doctrines were replaced by dialectic scholastic medicine, but the

College of Salerno brought to the West a system of professional medical practice which has since prevailed in all parts of the civilized world.

A New Kind of Museum Exhibit

THE New England Museum of Natural History in Boston, Mass., has been the first to turn a trade innovation in lighting to the service of museum galleries. In the particular case described by Bradford Washburn in the *Museums Journal* (39, 450; 1940) you gaze at a stoat watching you from the edge of a summer wood. As you look, the lights fade, become momentarily dim, and when the full light shows again the summer scene has gone, snow covers the ground, the trees are bare of leaves, and the stoats have changed into their winter dress of ermine. The case really contains two groups, a summer and a winter one; but the spectator looking at the summer group perceives it, when it is brilliantly lit internally, through a transparent sheet of Belgian 'black' glass. When the internal lights fade and the second group is illuminated, the black glass becomes opaque and acts as a mirror in which only the snow scene is visible, exactly overlapping the summer scene, of which it is a replica in reverse. Many technical difficulties had to be surmounted before the new exhibit was satisfactorily completed; but its dissolving habitat group at once made a great impression. One wonders if the average mortal really needs such bait in order to be induced to look at a representation of Nature: and the result—half his mind is thinking about the trick of the thing; only the other half is giving itself to the study of the Nature group.

Earthquakes Near Great Dams

ACCORDING to *Earthquake Notes* (11, No. 3; January 1940), earthquakes of varying intensity have been recorded from the neighbourhood of Boulder Dam since September 1936. During the first four months twelve shocks were felt, but the frequency increased until during April 1937 forty-five were felt. After this time the frequency increased until during the early part of 1939 there were on average two humanly felt earthquakes a month. The Wood-Anderson seismograph on the spot recorded more than five hundred disturbances during 1938. There has been some discussion among U.S. seismologists of plans for the observation of possible earthquakes in the neighbourhood of two other areas which will probably be similarly loaded. The first is the unfinished Grand Coulee Dam in the State of Washington, and the second is the proposed Shasta Dam near the confluence of the Pit and Sacramento Rivers in northern California. In the latter case there is yet time to obtain information of the seismicity of the area before loading. Similar data were not obtained in the case of the Boulder Dam.

Oxygen Administration and Inhalation Apparatus

A FIFTH memorandum in the Emergency Medical Services Series has been issued by the Ministry of Health entitled "Oxygen Administration—Indications, Methods and Types of Apparatus" (H.M. Stationery Office. 2*d*. net). The administration of oxygen is a valuable aid in the treatment of some forms of gas poisoning and lung disease, and in some surgical conditions such as shock and chest wounds. The memorandum incorporates the results of research on the subject, and is intended primarily for the guidance of medical officers in charge of hospitals. It describes the conditions for which oxygen therapy is likely to be effective, methods of oxygen administration, and the more important types of apparatus for the purpose, including a new form of nasal mask.

Alexander Pedler Lecture

THE Alexander Pedler Lecture, which is given annually under the auspices of the British Association, was this year delivered by Prof. Allan Ferguson before the Cardiff Naturalists' Society. The lecture, which was given in the Reardon Smith Lecture Theatre of the National Museum of Wales, Cardiff, on March 14, was entitled "Splashes, and what they Teach". It was chiefly concerned with an explanation of the phenomena attendant on the impact of a drop of liquid on a liquid or solid surface. A high-speed film was shown which illustrated the phenomena, and the results were compared with those of the earlier classical experiments carried out by the late Prof. Worthington.

Old Books on Social Sciences

WE have received a copy of Catalogue 54 published by E. P. Goldschmidt and Co., of 45 Old Bond Street, W.1, containing 307 items of old works dealing with a great variety of subjects. Attention may be directed to the following: Jacques Legrand's "Sophologium", a popular handbook of useful knowledge, possibly printed by Caxton, not later than 1473; Naudé's work on the principles of librarianship and library organization (1627); Beccaria's treatise on crimes and penalties (1766); Sir Edwin Chadwick's "Report on the Sanitary Condition of the Labouring Population of Great Britain" (1842); Patissier's work on factory hygiene and the diseases to which miners, industrial workers and others are exposed (1822); Schreiber's sixteenth century book on practical arithmetic, the first German book on the subject; Jérome de Monteux's treatise on hygiene, which contains chapters on dietetics, the care and nourishment of children, and a section on cosmetics (1559); Bernard Palissy's discourse on the nature of waters, fountains, rains, metals, salts, stones, earths and fire (1580), which entitles him to be regarded as one of the pioneers of modern chemistry and geology; Neander's "Tabacologia" (1626), the most important early work on tobacco; Villafranca's "Methodus refrigerandi" (1550), the earliest work on artificial refrigeration; and the first edition of Linnæus's book on the increase of the habitable earth (1744) bound up with the second edition of his oration on travelling in one's own country (1743).

Hydro-Electric Development in India

In Nature of January 6, p. 23, under this heading, it was stated that an irrigation scheme involving the generation of large quantities of electric power between the Punjab and the State of Bilaspur "is under construction". We are informed by the secretary of the Central Board of Irrigation that "the project referred to, namely the Bhakra Dam Project in the Punjab, is not 'under construction' but simply 'under consideration' at present".

Exhibition of Chinese Art at Leeds

An exhibition of Chinese art was opened in the Temple Newsham Mansion, Leeds, on March 23 by Dr. Thomas Bodkin, Barber professor of Fine Arts and director of the Barber Institute in the University of Birmingham. The exhibition consists of more than 200 specimens of pottery, paintings and bronzes, exhibited by the courtesy of Messrs. John Sparks of London, and on the initiative of the curator of Temple Newsham, Mr. Philip Hendy. Although the exhibition is, so far as possible, comprehensive in a chronological sense, the periods which will appeal most to students of the earlier phases of Chinese culture, covering the Shang-Yin (? 1766–1122 B.C.) and Chou (? 1122–249 B.C.) Dynasties and the Warring States, are represented by some notable exhibits forming a group of seven very rare bronzes. Three belong to the Shan-Yin Dynasty—two beaker-shaped vessels with a finely engraved design, and a sacrificial cup. There are also three vessels of the Chou Dynasty; and a dagger with a handle in the form of a mule's head is of the period of the Warring States (481–221 B.C.). Special interest is attached to these bronzes, all coming from burials. Among the most important of the pottery exhibits is the figure of a Lohan or Buddhist priest, seated with arms folded in the sleeves of his cloak, which stands about four feet high.

A Big Sunspot

A big sunspot has crossed the solar disk during the past week; appearing at the east limb on March 20, reaching the central meridian on March 26·3 and due to pass around the west limb of the disk on April 1. The area of the spot on March 23 was 1,000 millionths of the sun's hemisphere—an area well above the lower limit of size for naked-eye visibility. On March 23, a bright chromospheric eruption of considerable intensity was observed directly over the spot. A great magnetic storm began on March 23 and was in progress during the night of March 24–25, when the aurora was also seen in spite of bright moonlight. Widespread interference with both radio and cable communications was reported.

The Night Sky in April

During the month, night shortens by nearly two hours in the latitude of London. The moon is new on April 7 at 20·3h. and full on April 22 at 4·6h. On the latter date, a penumbral eclipse of the moon occurs, having been preceded on April 7 by an annular eclipse of the sun invisible in Great Britain, but to be seen in the southern parts of the United States of America. The penumbral lunar eclipse on April 22 begins at 2h. 27m., reaches a maximum phase (0·89) at 4h. 26m., and ends at 6h. 25m. In the nature of things, a penumbral lunar eclipse is not a spectacular phenomenon, but a difference in brightness between the east and west parts of the moon's disk should be discernible in a naked-eye scrutiny. In the evening skies after sunset, the brilliant planet Venus dominates the other planets still above the horizon—Mars, which is visible for about three hours after sunset, and Saturn, drawing nearer to the sun's position until it is in conjunction on April 24. Jupiter is now too close to the sun for observation, being in conjunction on April 11. It may be noted that also on April 11 at 0h. Venus is in conjunction with Mars; while at 19h. the moon, then nearly four days old, will be in conjunction with both these planets. The Lyrid meteors are due during April 19–22, the radiant point being near 104 Herculis. [All times are given in Universal Time; add 1 hour to convert to Summer Time.]

Announcements

Sir Harold Carpenter, F.R.S., professor of metallurgy in the Royal School of Mines, London, has been awarded the Honda prize of the Japan Metallurgy Society. He is the first foreigner to receive the award, which consists of a gold cup and £300.

Prof. A. V. Hill, M.P., F.R.S., has been appointed as assistant air attaché in Washington for special scientific liaison duties. The appointment is temporary, and has been accepted without remuneration.

The Messel Medal of the Society of Chemical Industry has been awarded to Lord Samuel. This medal, one of the two principal awards in the hands of the Society, is given in alternate years for "meritorious distinction in Science, Literature, Industry or Public Affairs, and who is prominently concerned with the Welfare of the Society". The presentation will be made at the annual meeting of the Society to be held in London on July 9, when Lord Samuel will deliver an address.

The Kitasato Institute for Infectious Diseases, founded at Tokyo, by Baron Kitasato, who discovered the bacillus of bubonic plague and who died in 1931, celebrated the twenty-fifth anniversary of its foundation on November 5.

According to Dr. C. Louis Leipoldt, medical secretary of the Medical Association of South Africa, in Southern Rhodesia where there are 188 registered medical practitioners, 116 are available for service in the present national emergency.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

IN THE PRESENT CIRCUMSTANCES, PROOFS OF "LETTERS" WILL NOT BE SUBMITTED TO CORRESPONDENTS OUTSIDE GREAT BRITAIN.

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 516. CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Human Genera and Species

PROF. OSMAN HILL's suggestion[1] that the classification of the Hominidæ is in urgent need of revision is likely to meet with general agreement. It is doubtful, however, if the particular proposals which he puts forward will do more than deliver the question from its present confusion—a confusion which at least has the merit of attributing a glamorous if unreal diversity to human ancestry—into another confusion at least as great. This is certain to occur if the principles of zoological classification are as he defines them. The differences which he suggests indicate generic distinctions ("differences in external or internal structure") cannot be regarded as essentially different from those which he believes to indicate specific distinctions ("differences in bodily proportions . . . differences in bodily form", etc.). For, quite apart from the verbal and logistic difficulty of deciding what is a difference in "structure" and what is a difference in "form", there is strong reason for supposing that pronounced differences in the one or the other or both aspects of the body or its organs are often simply due to differences in growth-rates. For example, some monkeys have a vermiform appendix, others lack this structure. Osman Hill's criteria suggest that differences of this kind are necessarily a sign of generic distinction. The difference, however, is entirely dependent on a different pattern and rate of growth in the cæcal region of the large intestine, that is, on a process which in this case leads to an extreme difference in bodily proportions. These, however, Osman Hill regards as indicative of specific and not generic distinction. It would therefore seem that no real difference separates his criteria for defining genera and species. In any event it is difficult to see how they could be applied to fragments of fossil human skulls.

It is because systematists have never succeeded in devising any standards of general application that zoological classification remains the somewhat uneven structure that it is. In spite of all attempts at suppression, the personal factor still enters largely into decisions that this or that group of animals constitutes a species of a genus. Some systematists are 'lumpers', others 'splitters', and however much it may be regretted as indicative of a lack of objectivity, Tate Regan's remark[2] that a species is something which a competent systematist recognizes as such still holds. But this does not mean that arbitrary conventions are not devised and used which allow of fairly equal generic and fairly equal specific subdivision within a given group of organisms. It was in the belief that this was so that I suggested in 1931[3] that there was no reason to regard Java man (Pithecanthropus) and Pekin man (Sinanthropus) as generically distinct. This view was reaffirmed last year by Le Gros Clark[4] and has just been re-stated by von Koenigswald[5] and Weidenreich.

Any rigid set of principles of systematic classification based, as Osman Hill's are, on a supposed application of principles derived from other fields of biology, usually defeats itself. One has to be particularly careful about such principles in the study of human origins because, as I have suggested elsewhere[6], the importance attached to this question, and the consequent and inevitable derivation of views on primate phylogeny from primate classification, make it essential that the genera within a single family, or the species within a single genus, should be at least approximately equivalent in their taxonomic differentiation, if the theoretical condition is to be fulfilled that the sub-groups of a given genus or family can be regarded as more closely related to each other by descent than they are to the members of other genera and families. This necessity applies to the whole field of palæontology. In a recent review of the problem, Arkell and Moy-Thomas[7] point out that every new genus and species of fossil should fit as nearly as possible into a uniform scale of classificatory values, and that classification should not be complicated by the introduction of preconceived, and usually arbitrary, views about phylogeny.

In the classification of the Hominidæ it is clear (*a*) that a difference which in one case serves as part of the basis for generic differentiation should be given equal consideration in another, and (*b*) that any common characters which bind the species of Homo into a single genus should not occur in any other genus of the Hominidæ. These are purely empirical and, to that extent, arbitrary criteria. But they are essential criteria if there is to be any order in the classification of the Hominidæ, and if views on human phylogeny are to be soundly based. The main difficulty that usually lies in the way of their application to the classification of any new human fossil skull is the desire to make too much of a good thing by magnifying its significance. This was certainly done, either consciously or unconsciously, in the case of the Pekin skull, and the only new fact which Weidenreich's recent announcement implies is that he has at last looked objectively at all the evidence which should have been taken into account at the start of his labours—for in my opinion[3] his conclusion was obvious from the moment Davidson Black published the measurements of the first two Sinanthropus skulls in 1930 and 1931[8], even though he, too, insisted on the distinctive generic separateness of the type. But in this, Black's successor in the excavations of Choukoutien has behaved no differently from almost every other discoverer of a fossil human skull, for the tendency to make too much of such a discovery appears to be irresistible.

An excellent example is provided by the recently described Swanscombe skull, which an impartial committee of experts set up by the Royal Anthropological Institute agreed, after exhaustive examination, differed in no significant way from modern human skulls[9]. In what amounts to a minority report, however, Marston[10], its discoverer, dissociates himself from this view and claims that the skull is much more primitive than this, even more primitive than the Neanderthal group!

If these controversies are to be avoided, it must be accepted by physical anthropologists that the species concept as used in systematics is artificial (however much meaning the term 'species' may have in another context, for example, ecological, as signifying a genuine biological unit), and that in consequence it is necessary to define the amount and kind of differentiation which, in the family Hominidæ, should determine either specific or generic status. At the present time there does not seem to be any more reason than there was ten years ago[3] for separating generically from one another in classification such archaic types as Sinanthropus, Pithecanthropus, Neanderthal and Rhodesian man. The only classification which still appears to be justified to-day is the separation of this group from a group comprising modern man, types belonging to the Upper Palæolithic, and such temporally aberrant types as the Swanscombe skull. The facts demand such a classification—whatever be its phylogenetic significance.

S. ZUCKERMAN.

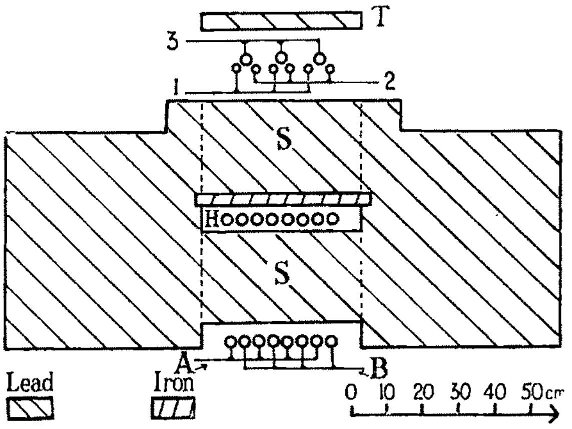
Penetrating Cosmic Ray Showers

It is now recognized that the majority of cosmic ray showers at sea-level consist of electron cascades (see, for example, Jánossy[1] and Lovell[2]). The present investigation gives evidence for the existence of a very small number of penetrating showers remaining after the cascades have been removed by suitable absorbers. The frequency of these penetrating showers, however, amounts only to a few per cent of all showers at sea-level. They therefore could not be detected in the experiments referred to above, or in the similar experiments of Schmeiser and Bothe[3].

The experimental arrangement is shown in the accompanying diagram. The counters shown joined with lines are connected in parallel, giving five-fold coincidences 1-2-3-*A*-*B*. Each five-fold coincidence registered corresponds to a shower containing more than one particle near the top counters as well as near the bottom counters. The eight counters *H* are placed in the middle of the absorber *S* in order to obtain evidence on the number of rays in the shower. These counters control small neon indicators in such a way that whenever a five-fold coincidence 1-2-3-*A*-*B* occurs, the lamps indicate the number *n* of the counters *H* which are discharged simultaneously with the coincidence. The neon flashes were recorded photographically. Some of the experimental results are collected in the table below.



Absorbers (cm. Pb)		Records containing *n* flashes (rate per 100 hour)		
T	*S*	$n = 0$ or 1	$n = \geqq 2$	$n = 0-8$
0	50	11 ± 2·5	8 ± 2	19 ± 3
Various thicknesses 1·8 – 10·0 cm.		32·5 ± 2·2	15·6 ± 1·6	48 ± 3

Since the bottom counters are effectively surrounded by 50 cm. of lead, each shower giving rise to a coincidence necessarily contained particles penetrating at least 50 cm. of lead whatever the direction of the shower particles.

It can be calculated that a cascade shower which penetrates 50 cm. of lead must have an initial energy of at least 10^{19} ev. If electrons or photons of this energy were sufficiently frequent to account for our observations, they would have to transfer an enormous amount of energy into ionization on their way through a lead absorber. This ionization can be shown to be larger than the total ionization produced by the whole cosmic ray beam, and would therefore be incompatible with the known rate of ionization. If, therefore, the Bethe-Heitler theory is valid for very high energies, the showers cannot be cascades.

A meson may produce two independent secondaries, one near the top and another near the bottom counters, and so give rise to a five-fold coincidence. In general, such a 'double knock-on' will give rise to a record $n = 0$ or 1, according as to whether the primary meson is, or is not, recorded by one of the counters *H*. In fact, the observed number of records $n = 0$ or 1 is in good agreement with the estimated rate of double knock-on processes. Only a small fraction of the double knock-on showers should produce independent secondaries near the counters *H* and so give rise to records with $n \geqq 2$. The observed rate of records $n \geqq 2$ is, however, more than 50 per cent of those with $n = 0$ or 1. We conclude, therefore, that the records with $n \geqq 2$ are *not* due to multiple knock-on showers. This conclusion would be invalidated if the cross-section for head-on collisions of mesons with electrons for energies above 5×10^{10} ev. should prove to be essentially larger than that calculated by Bhabha[4] or Massey and Corben[5].

Assuming, however, that the theories are correct, the records $n \geq 2$ must be interpreted as due to penetrating showers different from cascades and knock-on showers.

We have carried out experiments which suggest that these penetrating showers are connected with the extensive air showers. This is in agreement with the conclusions of Auger[6] and with recent experiments of Wataghin[7].

Though other interpretations cannot be excluded, it is plausible to assume that the observed showers contain several mesons simultaneously. The photographs of Braddick and Hensby[7] appear to show examples of two associated mesons.

Comparison of the coincidence rates for $T = 0$ and $T \geq 1{\cdot}8$ cm. shows that less than half the penetrating showers come from the air, while the rest are produced in the absorber T. It seems possible, therefore, that some of the observed showers are due to creation of mesons in the absorber T.

Origin of Visual After-Images

It is sometimes disputed whether visual after-images are due to retinal or central processes. Their retinal origin appears to be capable of demonstration as follows. If one eye is pressed with the finger or a spring balance near the outer canthus for about thirty seconds, it will become temporarily blind. This effect, known to Thomas Young, Helmholtz and Donders, is attributed to retinal anoxæmia. The pressure should be about 250 gm., applied over an area of 1 sq. cm. The easiest method is to press on top of the lids, keeping them sufficiently far apart to permit vision. A brown mist will spread over the visual field, and finally all objects will disappear. The image of a bright light, such as a 60-watt bulb, at a distance of 1 m. or 2 m. should now be thrown on a fixed region of the retina in the blind eye.

The easiest method is to fixate the light with the other eye; the natural convergence of the two eyes will cause the other to remain stationary though the pressure will prevent the image from falling exactly on the fovea. Such fixation is maintained for two minutes; the normal eye may be closed for a second from time to time, to make sure that the other eye is still completely blind. If, finally, the head is turned away from the light and pressure removed an after-image of the light will, of course, be seen with the normal eye on any suitable surface, being dark on a bright background and bright on a dark one.

If the normal eye be closed and the other opened ten seconds or so after pressure has been released, its vision will be found restored, and *an after-image positive or negative, will be seen against a suitable background, though the stimulation from the primary image has never reached the lower and higher visual centres at all.*

The image will usually be eccentrically placed in the visual field, through lack of normal fixation, and may be blurred or multiple owing to eye-movements. It may also be feebler at first owing to incomplete recovery of vision in the pressed eye. Under suitable conditions, however, its similarity to the image in the other eye leaves no doubt that both originate in the same way. This confirms the view that the positive after-image seen on a dark ground is due to retinal after-discharge, and the negative image on a bright ground to local reduction of retinal sensitivity. Since these effects occur despite anoxæmia, their photochemical origin is confirmed. The same result is obtained if the unpressed eye has been closed throughout, but fixation of the blind eye is then very difficult and there is no normal image for comparison. It is not denied that central processes may exert an inhibitory influence on these after-images.

Induced anoxæmia of the retina thus provides a useful method of blocking impulses between the retina and the visual centres and of isolating the contributions of different parts of the system to the sensory process.

Metabolism of Tumours

In a recent review[1] of the 1939 report of the British Empire Cancer Campaign, Dr. E. Boyland criticizes as "rather misleading" the following statement from the report of this Laboratory: "There appear at the present time to be two main points in which the metabolism of cancer differs from that of most normal tissues. Firstly the ability of cancer cells to form lactic acid persists even when the tissue is respiring, secondly cancer tissue has a respiratory quotient indicating that the oxidation of carbohydrate is abnormal".

This statement, far from being misleading, seems to me to be clear and correct: tumour tissue differs from most normal tissues in these two respects. In an earlier report[2] we had stated our view at length: following our findings[3] that kidney medulla has a powerful aerobic glycolysis not only in Ringer solution but also, contrary to György *et al.*[4], in serum, we said[2]: "In these somewhat rare cases, therefore, aerobic fermentation is certainly not associated with growth, still less with malignancy. Aerobic glycolysis is not specific for tumours, though practically all tumours have strong aerobic glycolysis". Later we studied cartilage[5] which we found[6] to have a similar type of metabolism. These are clearer examples than retina, since these tissues are probably no more damaged than in other tissue-slice experiments. Bone marrow glycolyses aerobically in Ringer's solution[7], though the preparation used by Fujita[2] had low aerobic glycolysis in serum.

Some of Dr. Boyland's other examples are less satisfactory. Liver[8,10], smooth muscle[10], diaphragm[11] and normal lymph glands[12,13,10] have all been reported with insignificant aerobic glycolysis compared with that of tumours. In fact, the transformation of normal liver into a hepatoma is a striking example[14,15] of the development from normal liver metabolism of "The type of metabolic activity characteristic of malignant tissue generally, that is, active glycolysis with a relatively high value for the aerobic glycolysis"[15]. This important result does not seem to favour the view that cancer tissue arises in general from normal tissue with a cancer-like metabolism.

Normal skin glycolyses aerobically and undergoes relatively little alteration of metabolism when it becomes papillomatous[16], but when muscle is replaced by malignant sarcoma a great increase of glycolysis occurs[16]. In observations of which details are not yet published, Berenblum, Chain and Heatley[17] found with isolated epithelium of skin and of Shope papilloma little difference of metabolism or of *R.Q.*, the latter being low in both. Thus their results on skin epithelium appear to resemble those of Bywaters[5] on synovial membrane. If we exclude retina, of which the *R.Q.* is controversial, these two examples represent the present exceptions among normal tissues to both our generalizations. Although both are tissues of low metabolic activity, it is likely that similar characteristics will be found in more active tissues as the search proceeds. It is clear that neither of our generalizations, nor both in combination, is in the strictest sense specific for tumours. Nevertheless, the association in tumour metabolism of relatively high aerobic and anaerobic glycolysis with the lowered *R.Q.* is such a constant one that to dismiss it is to discard as unimportant the most characteristic of established biochemical peculiarities of tumour tissue.

[17] *Ann. Rep. Brit. Emp. Cancer Campaign*, **16**, 215 (1939).

THE above letter contains two conflicting statements.

(1) "Aerobic glycolysis is not specific for tumours, though practically all tumours have strong aerobic glycolysis." This from Dr. Dickens's report of 1936 seems to be a fair and true statement of the position and not consistent with the following statement from the 1939 report, which I consider "rather misleading".

(2) "There appear at the present time to be two main points in which the metabolism of cancer differs from that of most normal tissues. Firstly the ability of cancer cells to form lactic acid persists even when the tissue is respiring."

Benign growths and most body tissues (with some exceptions, such as kidney cortex, spleen, ovary and lung) which have been carefully examined appear to have some aerobic glycolysis (for example. testis $Q_{L}^{O_2}$ 2·8–5·5, liver 0·9–4·3, uterus 3·0–6·9). Some of these non-malignant tissues, in addition to the three mentioned by Dr. Dickens, also have a lowered *R.Q.* A few malignant tumours, particularly some human carcinomata[1] and some spontaneous carcinomata in mice[2], have lower aerobic glycolysis than many 'normal' tissues.

There can be no doubt that the British Empire Cancer Campaign has in this, as in so many other problems connected with cancer, given most valuable help by securing the thorough investigation of the question in several different laboratories.

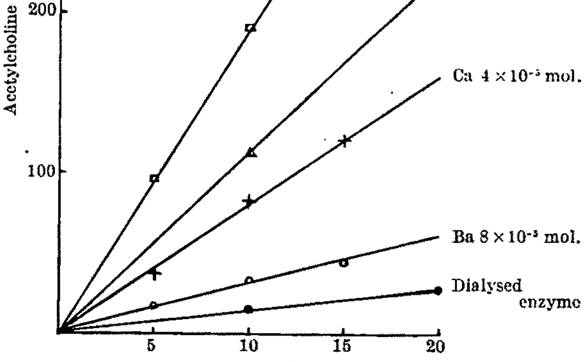
Action of Ions on Choline Esterase

THE physiological significance of choline esterase suggested by its high concentration at muscle end plates and at synapses of the central nervous system[1] makes it desirable to investigate the properties of the enzyme. The electric organ of Torpedo, which is considered as an accumulation of muscle end plates, has by far the highest content of choline esterase ever found in a tissue of fluid. An organ of 100–200 gm. weight splits about 200–400 gm. acetylcholine in 60 min., which is a hydrolytic power of the



ACTION OF DIVALENT IONS ON CHOLINE ESTERASE same order of magnitude as calculated for end plates. The organ has therefore been used as material for the preparation of active enzyme solutions[2].

Evidence obtained previously from these preparations indicated that the enzyme contains —SH groups essential for its activity[3]. The present investigations show that the enzyme is only active in the presence of divalent cations. After dialysis the enzyme practically completely loses its activity. A few γ of divalent ions reactivate it. The order of activation by the ions is as follows: Ba^{++}, Ca^{++}, Mg^{++}, Mn^{++} (see accompanying figure). Mn^{++} in a concentration of 0·00002 mol. (1·1 γ per c.c.) increased the amount of acetylcholine split in 60 min. from 0·08 to 1·13 mgm.

Meyerhof's co-workers described a strong effect of Mn^{++} on the action of cozymase[4] and cocarboxylase[5]. Mg^{++} was also active but to a smaller extent. v. Euler and his associates[6] observed that *iso*-citric dehydrogenase does not act unless Mn^{++} or Mg^{++} are present. In all three enzyme systems concentrations of the ions and relationships between the strength of Mn^{++} and Mg^{++} were similar to those described here.

The reactivation by cations occurs at a point different from that at which the reactivation by reduction of S–S groups takes place. The maximal effect of glutathione plus Mg^{++} is equal to the sum of the effects of each alone (see accompanying table).

SUM OF EFFECTS OF Mg^{++} AND GLUTATHIONE. MGM. ACETYLCHOLINE SPLIT IN 60 MIN.

	Values obtained	Calculated values
Dialysed enzyme	0·45	0·45
+ GSH 0·0003 mol.	2·20	+ 1·75
+ GSH 0·001 mol.	2·30	
+ Mg^{++} 0·002 mol.	1·85	+ 1·40
+ Mg^{++} 0·002 mol. + GSH 0·0003 mol.	3·67	3·60

Monovalent ions (Na,K) also reactivate the enzyme, but only at very high concentrations (0·1 mol.). However, even at such high concentrations the effect of the monovalent ions is much less than that of divalent ions. No difference has been found between K^+ and Na^+.

Our results and conclusions are in contrast to those recently described by Mendel *et al.*[7]. It should be borne in mind, however, that the enzyme preparations employed by those authors were obtained from horse serum and that they appear to have been less active and of a lower degree of purity than those previously described[2].

This work was aided by a grant of the Dazian Foundation.

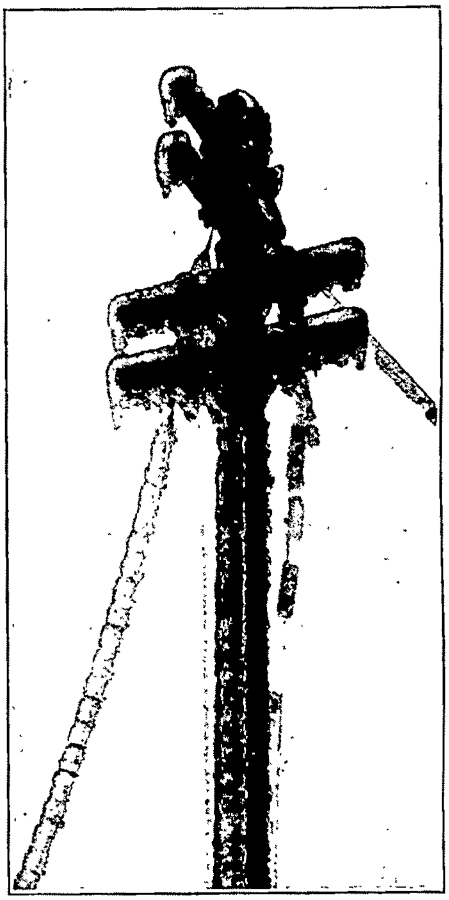
Ice Formation in Worcestershire

ON January 27, when the great snowstorm was developing, the Evesham district experienced a relatively light fall and this changed at night to 'supercooled' rain. Sunday, January 28, found us awaking to a strange 'creaking' of trees in the wind due, I found, to an armour of thick ice. Most of the ice was on top—my aerial had ¾ in. above, ¼ in. below. Wider exploration presented an amazing experience. Roads, walls, trees, hedges—everything was coated with inches of crystal clear ice. Branches and twigs were encased in ice many times their own diameter, and many were, like the telegraph wires in the accompanying illustration, either broken down or snapping as I passed. Slight rain was still falling and freezing instantly. There seems no doubt that rain had been falling all night in a 'supercooled' state, contact with objects initiating solidification, generally complete before the water could run underneath. People were chiselling their way into cars left outside, and ice on one near Broadway Tower was 6 in. thick.



I saw wood-pigeons, encased in ice as they roosted, hobbling through the grass. Presumably with the receipt of latent heat they had realized nothing untoward until attempting to fly. Roads themselves were sheets of ice—6 in. thick on Broadway Hill—and being used as skating rinks.

Quantitatively—ice 4 in. thick on twigs common, 'blades' of grass 4 in. thick; I measured one telegraph pole guy 18 in. in circumference; one branch weighed before and after thawing gave ratio 64 to 1, and on one fine grass blade the ice weighed 197 times the grass.

The whole appearance of the countryside was fantastic and grotesque, and it would be interesting to know if any previous similar occurrence is on record.

Evesham.

Optical Anisotropy of Cellulosic Sheets

THE following observations on the optical anisotropy of cellulose ester sheets may supplement the findings of Drummond[1].

Whether the 'slow ray' in the plane of the sheet is normal to, or coincident with, the direction of stress depends on the hydroxyl content of the ester, and, to a lesser extent, on the solvent content of the sheet when stress is applied.

Increasing hydroxyl content favours the same direction as that of the stress, whereas, as surmised by Drummond, introduction of acyl groups favours the normal direction. Thus, with cellulose acetates, the acetyl contents of which are greater than 43 per cent, the slow ray direction may be normal to the direction of stress ; similar behaviour is also shown by cellulose nitrate sheets.

Within a certain range of hydroxyl contents, in acetate and in nitrate sheets the amount of solvent or imbibed liquid when tension is applied may influence the position of the slow ray. In general, the slow ray lies normal to the direction of stress if tension is applied to a sheet which contains a large proportion of solvent, whereas removal of the latter favours its location in the direction of the applied stress.

The extrapolation of birefringence values of cellulose ester sheets to zero acetyl content by Drummond finds some justification from measurements made on uniaxial cellulose acetate sheets, where the increase in negative birefringence is approximately linear with a decrease from 44·8 to 27·0 per cent acetyl. This is more strictly the case in the triacetate region, provided a solvent is selected which gives relatively flexible sheets, and that esters of similar chain-length are employed. As might be anticipated, increase of chain-length increases the negative birefringence.

A detailed discussion of these results will be published elsewhere.

It may be opportune to emphasize here that this method of sheet birefringence determination[2] in its more accurate form is restricted to sheets of relatively low values of birefringence such as those which lie beyond the sensitivity of immersion methods. The method is essentially an approximation in two respects, first, in the assumption of identity of path of the two components in transmission through the sheet, and secondly, in the inherent approximation of the graphical extrapolation.

[2] Spence, J., *J. Phys. Chem.*, 43, 865 (1939).

Structure of Cellulose Acetate

RECENTLY I have examined several samples of cast plasticized secondary cellulose acetate sheet material under the microscope. With crossed nicols a uniform yellow polarization colour was shown, indicating a considerable amount of orientation. Taking the casting flow-lines, parallel to the 'selvedge' edge, as the direction of the *c* axis, the samples showed oblique extinction. This phenomenon is consistent with the view that the cellulose acetate unit, and also the parent cellulose, is monoclinic rather than orthorhombic.

Points from Foregoing Letters

L. Jánossy and P. Ingleby have carried out counter experiments which give evidence for the occurrence of penetrating showers distinctly different from cascades or knock-on showers. Parts of the showers may possibly be accounted for by assuming the creation of mesons in lead.

Mechanical pressure on the eye causes temporary blindness through retinal anoxæmia. K. J. W. Craik finds that after-images of a light exposed to the eye in this condition can be seen on releasing the pressure. This appears to demonstrate their retinal origin, since the stimulation from the primary image has never reached the visual centres in the brain.

In a reply by F. Dickens to a recent comment by Boyland, it is pointed out that although the association of a lowered respiratory quotient with a strong aerobic glycolysis is no longer considered as strictly specific to tumour metabolism, the occurrence among normal tissues of this combination is exceptional enough for it to remain the most characteristic of the known biochemical features of cancer. Dr. Boyland replies that, in his opinion, as this combination does recur in some cases, it is undesirable to say that tumours differ from non-malignant tissues in these properties.

Using enzyme preparations obtained from the electric organ of Torpedo, D. Nachmansohn finds that choline esterase is only active in the presence of divalent cations. Monovalent cations will reactivate the enzyme, but only at very high concentrations.

J. Spence points out, in regard to the anisotropy of cellulose sheets, that the hydroxyl content of the cellulose ester and the solvent content of the sheet influence the orientation of the slow ray in the plane of the stressed sheet. Uniaxial cellulose acetate sheets show, within limits, a linear increase in negative birefringence with increasing hydroxyl content.

RESEARCH ITEMS

Pleistocene and Prehistory in Europe and China

EXTENSIVE research by Wen-Chung Pei in the Chinese Pleistocene and comparison with corresponding results of European geologists and archæologists is summarized in "An Attempted Correlation of Quaternary Geology, Palæontology and Prehistory in Europe and China" (Institute of Archæology, University of London. Occasional Paper No. 2, 1939. Pp. 16+2 tables. 2*s*. 6*d*.). The object of the investigation was to arrive at the age of Sinanthropus, which is here assigned to the Lower Pleistocene in spite of the lithic industry, which exhibits a few features that in Europe do not appear until later. From the point of view of human evolution Sinanthropus would be contemporary with the European Eoanthropus and *Homo Heidelbergensis*. While the European Quaternary covers four main periods of cold climate, in China four physiographic cycles may be observed in which phases of erosion alternated with phases of sedimentation. From the geological point of view, Europe and China have two series of Pleistocene deposits in common, the older covering the period from late Pliocene to early Pleistocene, the younger characterized by the frequent occurrence of loessic material. These two series can be correlated in Europe and in China stratigraphically, lithologically and faunistically; but it is impossible to go further and into detail. It is premature, therefore, to base a correlation on geological evidence only. A purely palæontological basis, notwithstanding difficulties, is more satisfactory. The early Saumenian corresponds to Villafranchian, Choukoutien (Sinanthropus level) to Cromerian, Choukoutien III to early middle Pleistocene, Sjara-Osso-gol (Ordos) to Neanderthal, and Choukoutien Upper Cave to European Upper Palæolithic. Prehistory helps little, owing to differences of workmanship, but subject to this proviso, Choukoutien loc. 13 is contemporary with Abbevillian, Choukoutien loc. 15 with early Acheulean, early Clactonian and Tayacian, Ordos with middle and late Acheulean, Micoque, early and middle Levalloisian and Mousterian, and Choukoutien Upper Cave with upper Palæolithic—Aurignacian, Solutrean and Magdalenian.

Insulin Hypoglycæmia and the Central Nervous System

ERNST GELLHORN reported his investigations on the effects on the central nervous system of insulin hypoglycæmia before the recent meeting of the American Association. There is a close interrelationship between its effects and those of cerebral anoxia, in that the two states are mutually synergistic, and in both there is depressed cortical but augmented autonomic excitability. The resultant increased activity of the sympathetic system tends to restore the blood-sugar level, and at the same time to render the medullary centres less excitable, in this case by a direct action upon them of circulating adrenalin. Such reactions tend to restore the animal to its resting state, but may, under slightly different conditions, aggravate the effects of the changes. Thus, prolonged anoxia may prevent hypoglycæmic convulsions, but may also prevent the eventual restoration of a normal blood-sugar level by depressing the mobilization of the hepatic stores of glycogen.

Inheritance of Bobbed Hair

S. E. STODDARD (*J. Hered.*, 130, 543–545; 1940) reports a pedigree in man showing the inheritance as an autosomal dominant of a short fore-lock. The hairs of the fore-lock on the head of the affected individuals grow to five or six inches and then fall out, being replaced by new hairs which again reach 5½ inches and then fall out. This self-bobbing characteristic is to be called 'catatrichy'.

The Oldest Vertebrate Egg

FOSSIL reptilian eggs have been recorded from Cretaceous and Jurassic deposits, but they are rare, and the most striking discovery hitherto was the nest of dinosaur eggs found in the Desert of Gobi by Dr. Roy Chapman Andrews and his fellow-explorers. All earlier records are, however, much antedated by the discovery of an egg, 59 mm. long, at Rattlesnake Canyon, Archer Co., Texas, in rocks which lie close to the boundary between Carboniferous and Permian. Prof. Alfred S. Romer and Llewellyn I. Price describe the shell, almost 1 mm. thick, as ornamented with small rounded tubercles, and in section showing lamellæ, typical of amniote egg-shells (*Amer. J. Sci.*, 237, 826; 1939). The interior, as examined by X-ray photographs, showed no indication of embryonic development. Although it is impossible to say to what reptile the egg must be assigned, the most abundant of the four common reptiles of the Red-beds of Texas is the pelycosaur Ophiacodon (Theropleura), and the "chances are perhaps somewhat in its favor as the possible progenitor".

Growth Hormones in Seed Dressings

H. E. Croxall and L. Ogilvie (*J. Pom. and Hort. Sci.*, 17, 362; 1940) have shown that the application to pea and bean seeds of dry fungicidal dressings containing growth-promoting substances may be of considerable value. The vegetative growth of several different varieties of pea plants was stimulated by such treatments, but there was no difference in time of flowering. The dressings used consisted of talc, a proprietary mercurial dressing, and cuprous oxide, containing 5–20 parts per million of naphthalene acetic acid, mixed naphthylidene acetic acids and indolyl butyric acid. The rate of emergence of pea seeds sown in sterile soil in the greenhouse was accelerated, and the dry weight of the seedlings after three weeks growth was increased, by treating the seeds with the above dressings. In certain conditions, the development of some varieties of peas was checked by mercurial and cuprous oxide dressings. This check was partly or entirely overcome by the incorporation of growth substances. In field trials in summer, mercurial and cuprous oxide dressings alone reduced the crop when the soil was dry for a long period, but dressings containing growth substances gave yields up to 80 per cent greater than those from untreated seeds. In greenhouse soil contaminated with damping-off fungi, a higher percentage emergence from several varieties of peas, and one of dwarf beans, was obtained by treating the seeds with hormone-containing dressings than by the use of the same dressings without hormones. There was considerable difference in the response of different varieties to the dressings used.

Two Distinct Diaphorases

COENZYME-SPECIFIC dehydrogenases catalysing the oxidation of tissue metabolites such as lactic acid may require the presence of coenzyme I (diphosphopyridine nucleotide) or coenzyme II (triphosphopyridine nucleotide). Reduced coenzymes I and II do not by themselves react with oxygen, and a further link has been made by the demonstration of the presence in animal tissues of a 'coenzyme oxidase', named by Euler 'diaphorase' and by Dewan and Green 'coenzyme factor', which catalyses the oxidation of these reduced coenzymes I and II. Also, cytochromes *-a* and *-b* are rapidly reduced by the diaphorase – coenzyme system and re-oxidized by cytochrome oxidase and oxygen. The complete

thus :

-b ⟶ Oxygen

oscillograph. The results confirm those of previous workers that the electric field changes due to a lightning discharge include a slow field change due to the leader stroke, a rapid return stroke, and a final slow non-oscillating change. The disturbance is often followed by waves reflected from the ionosphere. In some cases a damped oscillating discharge was observed, and reasons are given for regarding this as a feature of the discharge rather than a result of successive reflections. A mean value of the peak power in an atmospheric is 5×10^5 kw., and of the total energy radiated 200 kw. sec. This is small compared with the total energy of a thundercloud.

INTERNATIONAL HEALTH INVESTIGATIONS

THE report to the Council of the League of Nations on the work of the thirty-first session of the Health Committee, November 20–24, 1939 (Special Supplement to Monthly Summary of the League of Nations, January, 1940), emphasizes the important duties of the Health Organisation under war-time conditions, particularly in view of the threats to health from movement of populations and evacuation.

The Committee agreed that the permanent health services should not be interrupted, particularly the Epidemiological Intelligence Service, the Singapore Bureau and the biological standardization
utility of which is universally
also desirable to contin
siderable amount of
out, such as the

water, and lower standards of living and hygiene. The Emergency Sub-Committee and the Health Section have accordingly been authorized to take such action as circumstances require, including a stocktaking of the armoury of preventive and curative weapons made possible by modern epidemiology, chemotherapy and serotherapy. The Health Section proposes to define the principles which should be followed in the control of those epidemic diseases which are regarded as the most
circumstances, for

out that any attempt to determine molecular weight of the protein by any of these means would yield abnormally large values.

In the sphere of host-virus relations, Ernest L. Spencer, of the Rockefeller Institute for Medical Research, demonstrated that the rate of virus multiplication is closely bound with the nitrogen metabolism of the host. Tobacco plants growing in pure culture, and supplied with a relatively large amount of nitrogen, allowed the virus to attain about five times the concentration found in normally fed plants. The effect was not due to an increased growth-rate of the plant, and it was also demonstrated with older seedlings. James M. Wallace, of Riverside, California, dealt with the development of resistance to the curly top virus of Turkish tobacco. *He showed that plants* recover from an attack by the virus, a certain time after inoculation. Such plants, when re-inoculated, do not again develop severe symptoms. Transmission from a recovered to a healthy plant by means of insect vectors induced severe symptoms in the healthy plants, but grafting merely transferred the mild symptoms typical of the recovered plants. Resistance, therefore, appears to be due to some interaction which is set up between host and virus.

S ASSOCIATION*

that the development or the preservation of aerial respiration in fishes of the tropical fresh waters was a response to the shortage of oxygen in the water, and that it occurred while the fish was still purely aquatic. The fish was then ready for the later changes which completed the migration. The stimulus for these was probably provided by the droughts to which any animal living in such waters must have been subjected. That this has been the course of the later stages of the migration on to the land is generally accepted, but it does not seem to have been so generally realized that the first stage in the process of migration was the evolution of adaptations to aerial respiration, first instigated by the lack of oxygen in the shallow tropical fresh waters in which the fish lived."

This presidential address in its printed form, with its extensive bibliography and liberal quotations from the work of other investigators, is to be [illegible] as a helpful handbook of reference [illegible] general biological interest.

ECOLOGY AND CO[illegible]

The basic principle underlying this method is the differential behaviour of a pest and its parasite under the same ecological conditions. This is illustrated by Shelford's work on the aphid, *Toxoptera graminum* and its parasite, *Lysiphlebus tritici*, and by the researches of several other workers. Even small differences in the rates of development of the host and parasite may cause the extinction of one or the other.

The control of malaria-transmitting mosquitoes by ecological methods has had undoubted success in certain areas and has possibilities of more general application. The fact that most of the vector Anophelines do not breed in sewage-polluted waters is exploited by turning industrial wastes, etc., into clean breeding waters. On the same [illegible]lling of pools and streams [illegible] ja, presiding over the Section of Botany, considered the peculiar group of algæ known as the Myxophyceæ. These algæ present many problems, both economic and botanical, and in spite of the extensive literature there is scarcely any authoritative statement that can be made concerning any aspect of their study at the present time. Owing to the peculiar properties of their cells, many of them are able to exist under high-temperature conditions and are largely tropical in their distribution, so that India is a particularly suitable centre for their study. With the active investigations that are being carried out by Prof. Bhâradwâja and other algologists at Madras, Lahore and Benares, it is hoped that much light will be thrown upon their peculiar features.

A special interest of this group for India is the way in which the Myxophyceæ at times undergo extreme development and give rise to the condition known as 'water-bloom'. On death and decay, such masses of algæ give disagreeable tastes and odours to the water and may render it unfit for drinking purposes, in fact there are records from many parts of the world of serious effects produced upon man and animals by drinking such water. In India, water-blooms are of common occurrence in ponds, pools and tanks, the water of which is used for consumption by humans and domesticated animals; though no serious effects have so far resulted in India, it is obviously a subject requiring investigation. Such points as the conditions favouring the development of the blooms, the contributing organisms, methods of control, and the manner in which the organisms persist all require workers in India.

Prof. Bhâradwâja also directed attention to the problems played by Myxophyceæ in soil ecology. These algæ occur in considerable numbers in the soil flora and some of them, notably Nostoc and Anabæna, are capable of nitrogen-fixation. In the Indian rice fields, the same crop is grown year after year without addition of manure, and it has been discussed whether the abundant development of these algæ during inundation may be a factor of any importance. Fritsch and De came to the conclusion that their part in this connexion was probably relatively insignificant, but the problem needs further study.

*Continued from page 471.

[illegible] many cases the generic distinctions are unsatisfactory, as they are not applied logically and allow of too much intergrading. Their cytology has received considerable attention lately and most workers are now agreed that the central body may be regarded as a nucleus.

Systematic study of the group involves such problems as their relation to the isolated group of the Chamæsiphonales and also to the Bacteria, especially such types as the sulphur bacteria.

Prof. Bhâradwâja's address points out the wide scope for workers in this field, and his survey of the present position of knowledge of the group will be a valuable basis for anyone attracted to further the study of the Myxophyceæ.

AIR-BREATHING FISHES

The presidential address to the Section of Zoology was delivered by Prof. B. K. Das.

In a comprehensive survey of present knowledge of the phenomenon of 'air-breathing' in fishes, Prof. Das developed the theory of structural adaptation in response to environmental change. "The habit of swallowing air," he says, "being long continued, becomes deeply engrained in the constitution of the species, generations after generations, and is gradually improved and eventually leads to structural modifications, usually in the form of reservoirs adapted to lodge the inhaled air. These reservoirs are of very different forms and quite independently evolved, in each and every species of fish. . . ."

Six main types were described of progressive adaptations, which are to be seen in modern air-breathing fishes, namely, modifications of the buccopharynx; pharyngeal 'lung'; opercular chambers; opercular 'lung'; specialized parts of the alimentary canal (stomach and intestine); and the air-bladder. These accessory respiratory organs are regarded as the physiological forerunners of the true lungs of the terrestrial vertebrates, evolved in consequence of a lack of oxygen in the water.

The views of Carter and Beadle are supported and quoted verbatim: ". . . A power of breathing air must have been a necessary preliminary to the possibility of migration to land. It appears probable to the Section of Entomology, discussed the general principles of insect ecology and, in particular, the application of such knowledge to insect control. As he pointed out, if we know the conditions of environment of an insect pest and the influence of changes thereof on its population, it may be possible to predict the outbreak of the pest in advance or to evolve methods which would keep the injurious species under control. Of the various physical factors of environment, temperature is undoubtedly the most important single agency. In order to illustrate the influence of this factor and to indicate how such information can be utilized by applied entomologists, examples are given of Zwolfer's critical work on the nun moth, *Lymantra monacha*, of Bodenheimer's studies on the Mediterranean fruit-fly and of several other works.

Next in importance to heat, the fundamental necessity of insects, as of other animals, is the moisture content of their environment. Too low or too high humidity is injurious to their existence. On the basis of such information, the Imperial Agricultural Research Institute has shown that good and well-spread rains do not reduce the spotted boll worms of cotton directly, but indirectly by raising the atmospheric humidity, which is inimical to the bollworm and conducive to the multiplication of its parasite *Microbracon lefroyi*. Afzal Husain and Haroon Khan's work on the ecology of pink bollworm of cotton in the Punjab illustrates the combined effect of temperature and humidity on insect prevalence. They found that temperatures between about 18° C. and 26° C., with a relative humidity of more than 70 per cent, are most suitable for egg production and oviposition. Those parts of the Punjab where temperature and humidity conditions approach the above figures during July–October, which is the active period of the pest, are badly infested with the bollworm, while in canal colonies and the western Punjab, where the conditions are different, the pink bollworm does not occur as a pest.

Insects are not only exposed to climatic factors but also to biotic factors such as parasites, predators, competitors, types of surrounding vegetation, etc. The importance of natural enemies in reducing the population of insect pests is well known and is being exploited by workers on biological control of pests.

once appears and begins to [redacted] of streams by growing low hedges of lantana, etc., is being extensively practised in India, Malaya and other countries. These observations also emphasize the necessity of preserving original shade and adding more trees to natural jungle as an anti-malaria measure.

Dr. Pruthi's address, it may be added, is well documented with a bibliography of the literature bearing upon the subjects under discussion.

ANTHROPOLOGICAL AND ARCHÆOLOGICAL STUDIES IN INDIA

The presidential address to the Section of Anthropology was delivered by Rao Bahadur K. N. Dikshit, who discussed "The Scope of Prehistoric and Anthropological Work in India".

It is to be hoped that the association between archæology and anthropology which has been exemplified in this session of the Indian Science Congress will be a more abiding one, and will react to the mutual advantage of both the sciences, and that all universities and research institutions, which have provided facilities for work in one, will always extend them to the other branch of humanistic studies. In this vast country there is unlimited scope for these studies, and the danger from the extension of cultivation and rural expansion in a more sophisticated mode of life is equally felt by both. It is, therefore, all the more necessary that the future research programme should be speeded up and properly co-ordinated.

So far as expenditure is concerned, although archæology looms somewhat large among the scientific departments of the Government of India, an infinitesimal amount is available for expenditure on work of a scientific character. The personnel ought to be strengthened with a view to the extension of scientific activities in prehistoric archæology and anthropology. Many of the museums are doing good work in the educational sphere, but there is scarcely any scope for the acquisition of scientific knowledge regarding man and very few research facilities.

Sir Leonard Woolley has directed attention to the want of sufficient contact between the Archæological Department and the anthropologist. He has

INTERNATIONAL UNITY IN WAR AND PEACE

THE solemn declaration of the Supreme War Council issued in London last week states firmly and explicitly what most people have taken for granted about the unity of the Allies in war and in the making of peace. It should now be clear to the whole world that their unity is firmly established, and that it is not merely a contribution towards winning the war but will also constitute the sure and stable foundation of an enduring peace. The two Governments, desiring to extend the scope of agreements concluded last December to all spheres affecting the interests and security of the two nations, mutually undertake that they will neither negotiate nor conclude an armistice or treaty of peace except by mutual agreement, and that they will not discuss peace terms before reaching complete agreement on the conditions necessary to ensure to each of them an effective and lasting guarantee of their security.

The final declaration is even more significant. The two Governments undertake to maintain, after the signing of peace, a community of action in all spheres for so long as may be necessary to safeguard their security, and to effect the reconstruction, with the assistance of other nations, of an international order which will ensure the liberty of peoples, respect for law and the maintenance of peace in Europe. The terms of this declaration are strikingly in harmony with the recent declaration of President Roosevelt, and on that ground alone are reassuring to neutral as well as Allied, opinion and likely to promote Anglo-American understanding and good relations. More important still, confirming Sir John Simon's statement in a recent broadcast that the close Anglo-French co-operation established in every field will continue when the War has ended, it encourages the hopes which have been placed in Anglo-French co-operation as a stepping-stone to a new world order.

The declaration is open to no other interpretation than that the two Governments have accepted the responsibility for a further task when their joint forces have won for them security and the guarantee that it will endure—the organization of a new international order, capable of preserving law, liberty and peace for all nations. Already the co-operation between the two nations in the prosecution of the War itself has led them to give up their absolute sovereignty. That part of their sovereignty which they have surrendered into the common fund of authority is now to remain there at least until the new international order has been established.

This declaration, therefore, amply justifies the hopes of those who saw in the Supreme Council and the Allied High Command the germ from which might develop an international organ of government with an international police force at its command. In the light of it, again, arrangements recently concluded between the British and French Colonial Offices for pooling information and advice on problems of government in Africa may well form the basis for an extension or evolution of the mandates system, which may provide the world with an adequate and just settlement of the problems of colonies and access to raw materials. Similarly, the experience gained in the working of the economic and financial agreements will be of incalculable value.

This declaration justifies the strongest hopes of those who are concerned with the establishment of a new and enduring world order which will safeguard the liberty of peoples and respect for law, on which human progress in whatever field has been based, and indicates that, when the time comes to discuss larger systems of co-operation, Anglo-French collaboration will provide us with an invaluable store of wisdom on the community of ideas necessary for co-operation to be possible, and on the ends to which co-operation is desirable and possible. Already it shows us that some of the gravest weaknesses of the Treaty of Versailles and of the Covenant of the League of Nations will be avoided. The framework or constitution of the new world order will be attempted by a separate and subsequent act to the framing of the terms of peace. The declaration of March 28 may well come to assume historic significance in the evolution of world order, both as marking a stage towards the renunciation of absolute national sovereignty and in the linking of the distinctive political genius of two entire peoples in building up a system of co-operation to serve their own immediate purposes and also those of all other States subscribing to like ideals of law and justice, of freedom and humanity.

EDUCATION IN THE ARMED FORCES

IN his review in the House of Commons on March 13, the Minister of War directed attention to developments in the provision of educational facilities for men in the Armed Forces. Mr. Stanley outlined the general scheme which is in operation under the ægis of the Central Advisory Council for Adult Education in H.M. Forces (Home Services), which was brought into being a few months ago. The Council is representative of organizations for adult education, and works in conjunction with regional committees set up by the vice-chancellors of universities or principals of university colleges in their own areas. The Board of Education acts as the medium through which the Central Advisory Council makes contact with the Admiralty, War Office, and Air Ministry, while the divisional inspectors of the Board take a similar part with the regional committees. The Central Advisory Council had appealed to the War Office for a sum of £10,000 "to be going on with", and help on a similar scale is being requested from the Admiralty and Air Ministry. The outcome of these applications is not clear and was not dwelt upon by Mr. Stanley in his statement, although the omission suggests that the applications have been at least temporarily shelved. It is essential that the existing situation should be clarified if misconceptions are to be avoided.

At its initial meeting, adequate testimony was reported by the Central Advisory Council to show that men and women in the Services are in pressing need of educational facilities of all kinds, including lectures and discussions, books and correspondence, and other services that have been fostered by adult education associations. The need of men and women in the Services for mental stimulation as well as for welfare and recreational facilities has frequently been neglected, a danger of which full cognizance must be taken to-day. This was not generally realized until the closing stages of the War of 1914–18, and not until 1920 was the Army Educational Corps founded as a permanent organization.

The objects of educational services were stated in an Army Order of September 24, 1918, to be: (*a*) to raise morale by indirectly providing mental stimulus and change, and directly by means of lectures on German methods, guns, etc.; (*b*) to broaden and quicken intelligence both by stimulating a desire for study and by giving men a wider realization of their duties as citizens of the British Empire; (*c*) to help men in their work after the War by practical instruction, so far as may be possible, in their professions or trades. When later the various educational schemes were introduced, they were eminently successful; their earlier introduction might have prevented much of the confusion that followed demobilization. Since that time, adult education has made such great strides that many men and women of the Forces to-day have been accustomed to lectures and discussions. The adoption of adequate educational measures is a matter of urgency, and one which should, if carefully planned, lead to the extension of democratic principles in a way which previously has been impossible.

The types of lectures that are likely to be most popular for men and women in the Forces have already been carefully investigated. The early experiments of the Central Advisory Council showed that the needs of the Services fall into three main groups: (1) a great demand for single lectures by authorities on such subjects as foreign affairs, history, exploration, literature suggested the possibility of unravelling the problems of the past by significant survivals among existing peoples, as, for example, the ancient burial customs in South India. A common plan pursued by workers in the field should, he holds, result in a more intelligent collection of anthropological material, and the task of the archæologist would be made simpler if the museums of India were to collect and preserve, not only ancient pottery and handiwork, but also that produced up to to-day by the primitive peoples of India. The idea of a central ethnological museum in New Delhi unfortunately has been allowed to lapse, and India is still without either an anthropological, ethnological or archæological central museum.

Turning to the field of prehistoric archæology, it is now more than seventy years ago that the first human artefacts associated with the bones of extinct mammals were found in the cliffs of the Nerbada and the Godaveri. It is unfortunate that further investigations were not carried on in the light of new discoveries in every part of the world. The attention of the Government and the universities should be directed towards the necessity of the systematic conduct of such work under trained prehistorians. It is unfortunate that the systematic survey of the Yale-Cambridge expedition under Dr. H. de Terra has not been continued.

The most interesting and well-developed phase of the prehistoric civilization of India undoubtedly is that represented by Harappa and Mohenjo-daro. It is unfortunate that there is no prospect of further work in this field to discover tribes with earlier and later cultures. Further systematic work at Dambbuthi would be rewarded with rich results unravelling an earlier civilization than Mohenjo-daro, whereas bridging the gap between Mohenjo-daro and later civilizations will occupy generations of workers.

The problem of Aryan invasion has as yet received no light from excavation in Sind and the Punjab, while the proper study of the sequence of metallurgical knowledge has yet to be established, and the place of the copper culture of the Gangetic valley and the iron industry of, for example, Bellary in the south has yet to be determined. Further research alone will show what the exact relation between the stone and metal ages of North and South India must have been.

In South India, the scope for work is greater owing to the abundance of material suitable for the manufacture of tools for palæolithic and neolithic man; while in every district one or other phase of pre- and protohistory is present in examples which must be systematically studied before many of them meet destruction at the hand of man. Among such subjects of research are the rock-shelters and the rock-paintings and carvings which lead up to the culminating splendours of Ajanta and Bagh.

One of the greatest difficulties facing the physical anthropologist in India is that of obtaining material for determining the racial characteristics of the ancient people of their country. The dearth of students in this highly interesting branch of knowledge is very keenly felt. In anthropometry, much interesting work has been done in the various provinces and among the different castes or tribes; but it is no exaggeration to say that barely the fringe of the problem has been touched. For the anthropologist there can be no more interesting country than India to study, although he would probably be overwhelmed by the immensity of the task and the diversity of the material before him. When in India every stage of the entire progress of the human race from the humblest beginnings to the greatest spiritual elevation can be studied with greater ease and facility than in any other country, is it too much to expect that the proud possessors of this wonderful heritage will not neglect their patrimony and will not leave entirely to others the task of studying themselves, their racial composition and age-long cultures ?

CROP PRODUCTION IN INDIA

The presidential address to the Section of Agriculture was delivered by Prof. Jai Chand Luthra, who took as his subject "Some Problems of Crop Production in India". Prof. Luthra began by reviewing the condition of Indian agriculture up to the time when the Government took steps to organize some aspects of it on scientific lines, that is about the beginning of the present century. He stressed the fact that India's farm produce is meant primarily for local consumption, and agriculture must therefore remain India's basic industry; there is, however, a demand for the establishment of secondary industries, such as those processing grain for breakfast food.

In the nineteenth century agriculture suffered a setback, of which the chief cause was the indifference of the farmer to the quality of seed. This neglect is of comparatively recent date, for at one time India was famous for the fine quality of its cotton. The merit and the constitutional structure of seed is of fundamental importance in crop husbandry. In India there is no legal safeguard of germination percentage, and pressing need is felt for a Seeds Act. Prof. Luthra reviewed some factors bearing on seed quality. Experiments at Lyallpur have shown that a predominance of yellow in the seed of berseem is an indication of maturity and of good germination; and the proportion of yellow seed bears an inverse relation to the number of cuttings taken from the crop left to seed. A similar correlation of colour to viability has been observed in seeds of shaftal (*Trifolium resupinatum*) and of lucerne.

Selection and breeding have done a great deal for Indian agriculture, but have brought about peculiar difficulties. One of the most important crops of the Punjab and the United Provinces is gram (*Cicer arietinum*). When the two best gram selections, evolved after twenty-five years work, were introduced into cultivation, blight disease was confined to the northern part of the Punjab. For the last four years, gram in other parts of the province has been stricken so severely by blight that one popular selection has been affected up to at least 50 per cent. The growers get alarmed when they find crops damaged by unaccustomed diseases, and it is no wonder if the growers remark that agricultural departments create the diseases. However, in Burma the serious wilt of gram has been overcome by the discovery of a resistant type that now occupies the entire area under that crop.

The wealth of India lies in its innumerable villages; as Tagore has said, "In the keeping of the village lies the cradle of the race". For effecting real improvement in agriculture, it is necessary to take stock of the economic conditions of the farmer. The village is working under many disabilities. There is everywhere an earnest desire that the farmer should raise his standard of living, but so long as he is unable to increase his earning power this will remain a wish. Some measures are necessary for affording relief to the growers of food crops. In the Punjab the average size of a cultivated holding is scarcely 10 acres, and as many as six or seven persons live on it. Considerable labour is therefore being wasted on an unremunerative occupation.

NUTRITIVE VALUE OF RICE

Dr. W. R. Aykroyd devoted his presidential address to the Section of Physiology to the subject of rice. Rice is the staple food of the majority of the population in the provinces of Assam, Bengal, Bihar, Orissa and Madras. The diet of many other peoples in the East is also based on rice; in fact, it is stated that rice is the staple food of about half the human race. Yet, by modern standards, the rice-eater's diet falls short of such standards in almost every important constituent. In India he consumes in addition to his staple cereal, which supplies 80–90 per cent of the total calories, only very small quantities of other foods such as pulses, vegetables, fruits and meat; milk and milk products are taken in negligible quantities or not at all.

Rice, compared with most cereals, has a low protein content, although the proteins are of high biological value. It is poor in fat and carotene, calcium and iron; the amount of phosphorus present is fairly high. Milling reduces all the above constituents; in many parts of India, however, rice is prepared for consumption by hand-pounding, when the losses are less. Hand-pounded rice retains 50–75 per cent of the pericarp, the germ being usually completely removed. Raw rice when milled loses about three-quarters of its vitamin B_1 and two thirds of its nicotinic acid; these losses are considerably reduced if the rice is parboiled first. Parboiling is the steaming or boiling of unhusked rice after soaking; this splits the woody husk and renders its subsequent removal easier. After parboiling, the rice is pounded or milled in the same way as raw rice; during the steaming some of the vitamin B_1 and nicotinic acid diffuses through the grain and cannot be removed by subsequent milling. This fact is of great importance and, since most of the rice-eaters in India consume parboiled in preference to raw rice, explains the relative rarity of typical beriberi in most parts of the country. Washing the rice results in further losses of essential foodstuffs. The losses are of the following order: calories, 15 per cent; protein, 10 per cent; iron, 75 per cent; calcium and phosphorus, 50 per cent; vitamin B_1 and nicotinic acid, 40–50 per cent.

Dr. Aykroyd finally considered how rice diets can be improved. He is of the opinion that the development of strains of high nutritive value is unlikely to improve rice diets, since rice will always be deficient in certain food factors. He considers the easiest way of raising the nutritive value to be by minimizing the losses brought about by milling, washing and cooking. On the other hand, the introduction of high-yielding strains will reduce the pressure on the land and enable the production of supplementary foods to be increased. When parboiled rice is consumed, there is little difference in nutritive value between hand-pounded and machine-milled, although the former is to be preferred. Highly milled raw rice is a danger to public health, and its use should be discouraged. Dr. Aykroyd suggested that milling beyond a certain degree should be prohibited; a suitable standard might be not less than 1·5 μgm. of vitamin B_1 per gm. Once-polished raw rice has a vitamin B_1 content of this order; use of such a rice would prevent the appearance of beriberi.

Rice must, however, be supplemented by other foodstuffs. Dr. Aykroyd suggested that ragi, a millet, should substitute rice in part, and that the intake of pulses and green leafy vegetables should be increased; the latter supply vitamin A and calcium. Milk is the best supplement to rice diets; if fresh milk is not available, milk reconstituted from skimmed milk powder may be recommended. Milk supplies calcium, or this element can be provided in the form of calcium lactate; such a supplement (about one gram daily) definitely improves the state of nutrition of children on a rice diet. Vitamin A can be provided in green leafy vegetables, milk-fat, fish liver oil or red palm oil. Dr. Aykroyd suggested that it might be possible to blend the latter with common Indian vegetable oils to produce a palatable product with a vitamin A activity corresponding to that of good butter. Finally, he emphasized that the development of an efficient fishing industry would provide India with a valuable supplement to poor rice diets.

PSYCHOLOGY AND EDUCATIONAL RESEARCH

In his presidential address to the Section of Psychology, Dr. D. D. Shendarkar said that although psychology is a comparatively young science, yet it has already found application in many fields, of which education is of vital importance. Results of investigations into such educational problems as scholastic and intelligence tests, examinations, and learning processes, are evidence of the value of psychological methods and knowledge to the efficiency of the teacher. Education is becoming more scientific in method. The suggestion, though, of practical problems and the testing of the experimental results in actual practice must rest with the teacher. Unfortunately, the psychology taught in training colleges for teachers is often too theoretical, and the young teacher does not see the connexion between the science and the problems of the class-room.

There is an urgent need for a central institute of education where training in research methods could be obtained, and where modern research sources in educational topics would be available for reference. Such a body would serve both as a training and consultative body as well as a centre for research. Although learning is the central problem in education, yet research into the learning processes is inadequate, largely because experiments in learning have been studied in psychological laboratories, and the materials employed have too often been of an artificial nature. Research into testing for intelligence has yielded practical results, and now intelligence tests are used in selection for admission to different types of schools, for vocational guidance, and for diagnosing feeblemindedness and backwardness. The problem of admission to different types of higher secondary schools is in reality one of discovering the type of education most suited to the capacities and interests of the pupils, so that they may be classified according to mental ability rather than according to scholastic attainments. Little, however, is known of the abilities required for the various vocations.

Psychology has made considerable development in regard to children's problems and child guidance, and it attempts to diagnose and treat the underlying causes of the various symptoms instead of dealing with the symptom alone. The utilitarian study of psychology has not, however, kept pace with its academic study; what India needs at the present juncture is that the knowledge available should be applied.

SEVENTY YEARS AGO

NATURE, vol. 1, March 31, 1870

The Size of Atoms

"The idea of an atom has been so constantly associated with incredible assumptions of infinite strength, absolute rigidity, mystical actions at a distance, and indivisibility, that chemists and many other reasonable naturalists of modern times, losing all patience with it, have dismissed it to the realms of metaphysics, and made it smaller than 'anything we can conceive'." "W.T." then goes on to review the experimental evidence for giving tangible sizes to atoms. He refers to Cauchy's mathematical work, and to investigations on the contact electricity of metals on capillary attraction as shown by soap bubble investigations, on the kinetic theory of gases, and sums up as follows:

"The four lines of argument which I have now indicated, lead all to substantially the same estimate of the dimensions of molecular structure. Jointly they establish with what we cannot but regard as a very high degree of probability the conclusion that in any ordinary liquid, transparent solid, or seemingly opaque solid, the mean distance between the centres of contiguous molecules is less than the hundred-millionth, and greater than the two thousand-millionth of a centimetre.

"To form some conception of the degree of coarse-grainedness indicated by this conclusion, imagine a raindrop, or a globe of glass as large as a pea, to be magnified up to the size of the earth, each constituent molecule being magnified in the same proportion. The magnified structure would be coarser grained than a heap of small shot, but probably less coarse grained than a heap of cricket-balls."

Bacterial Warfare

Prof. Tyndall will have much to answer for in the results that may be expected from the spread of his "dust and disease" theory. It is stated by the *Athenæum* that a new idea has been broached in a recent lecture by Mr. Bloxam, the lecturer on chemistry to the department of artillery studies. He suggests that the committee on explosives, abandoning gun cotton, should collect the germs of small-pox and similar malignant diseases, in cotton or other dust-collecting substances, and load shells with them. We should then hear of an enemy dislodged from his position by a volley of typhus, or a few rounds of Asiatic cholera. We shall expect to receive the particulars of a new "Sale of Poisons" Act, imposing the strictest regulations on the sale by chemists of packets of "cholera germs" or "small-pox seed". Probably none will be allowed to be sold without bearing the stamp of the Royal Institution, certifying that they have been examined by the microscope and are warranted to be the genuine article.

A course of lectures for women in the science and practice of music, by Mr. Sullivan, will be delivered at South Kensington, under the patronage of the Science and Art Department, shortly after the close of Prof. Oliver's course on botany.

In speaking of the extinction of species and the struggle for existence, Mr. Darwin uses language which may be literally applied—applied without even verbal modification—to the phenomenon of languages. [From an article by Dean Farrar.]

UNIVERSITY EVENTS

London.—The title of reader in physics in the University has been conferred on Dr. F. C. Chalklin, in respect of the post held by him at University College.

The degree of D.Sc. has been conferred on Mr. Hugh Davson (University College), Mr. J. L. D'Silva (King's College), Dr. W. H. Newton (University College), Prof. Gilbert Stead (Guy's Hospital Medical School), Mr. Albert Wassermann (University College), and that of D.Sc. (Engineering) on Mr. R. H. Barfield (Imperial College).

Manchester.—Dr. C. W. Wardlaw, officer-in-charge of the Low Temperature Research Station, Imperial College of Tropical Agriculture, Trinidad, has been appointed Barker professor of cryptogamic botany in succession to Prof. W. H. Lang, who retires at the end of the present session.

Reading.—Dr. Barbara Colson, formerly research assistant in botany in the University of Manchester, has been appointed lecturer in botany.

FORTHCOMING EVENTS

Saturday, March 30

Royal Photographic Society, at 3 p.m.—H. Mills Cartwright: "Colour Photogravure by the Masking Method".

Tuesday, April 2

Royal Horticultural Society, at 3 p.m.—Prof. F. E. Weiss: "Graft Hybrids and Chimæras" (Masters Memorial Lectures. Succeeding lecture on April 16).

Thursday, April 4

Chemical Society, at 2.30 p.m.—Annual General Meeting. At 3 p.m.—Sir Robert Robinson: "Some Biological Aspects of Organic Chemistry, (a) Recent Progress in Chemotherapy, (b) Structural Relations in the Sterol Group" (Presidential Address). At 5 p.m.—Prof. E. K. Rideal: "The Sörensen Memorial Lecture".

Friday, April 5

Institution of Chemical Engineers (Eighteenth Annual Corporate Meeting, at the Hotel Victoria), at 11.45 a.m.—F. Heron Rogers: "Oil" (Presidential Address).

British Psychological Society (Extended General Meeting), April 5–6.

April 5.—Discussion on the Problems of Evacuated Children (Speakers: E. M. Bartlett, A. H. Bowley, C. Preston Rawson).

April 6.—Discussion on Propaganda (Rex Knight: "The Technique of Propaganda"; F. M. Austin: "Propaganda and Suggestion").

April 6.—Discussion on So-called War Neuroses (Speakers: Millais Culpin, T. A. Ross, Edward Glover).

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer in Mechanical Engineering at the Bradford Technical College—The Director of Education, Town Hall, Bradford (April 6).

Graduate Teacher of Mechanical Engineering Subjects in the Smethwick Municipal College—The Chief Education Officer, Education Offices, 215 High Street, Smethwick (April 8).

Chemist in the Waterworks Department—The Secretary, Waterworks Offices, Town Hall, Manchester 2 (April 15).

Professor of Chemistry—The Principal, Heriot-Watt College, Edinburgh (April 16).

Head of the Matriculation Department—The Director of Education, The Polytechnic, 309 Regent Street, W.1 (April 16).

Temporary Lecturer in charge of the Department of Physics—The Registrar, University College, Leicester (April 17).

AN ASSISTANT MASTER to teach Geography, Mathematics, Elementary Science and Woodwork at the Rosario English School, Argentine —The British Council, 3 Hanover Street, W.1 (quoting 'Rosario') (April 17).

PRINCIPAL OF THE CEYLON UNIVERSITY COLLEGE—The Director of Recruitment (Colonial Service), Colonial Office, 29 Queen Anne's Gate, S.W.1 (April 30).

TEMPORARY FULL-TIME TEACHER OF ENGINEERING SUBJECTS—The Principal, Technical Institute, Ladywell, Dover.

ASSISTANT ENGINEER for the Drainage and Irrigation Department, Malaya—The Crown Agents for the Colonies, 4 Millbank, S.W.1 (quoting M/9114).

ASSISTANT TOWN ENGINEER for the Kumasi Public Health Board, Gold Coast—The Crown Agents for the Colonies, 4 Millbank, S.W.1 (quoting M/8332).

REPORTS AND OTHER PUBLICATIONS

(not included in the monthly Books Supplement)

Great Britain and Ireland

Scientific Proceedings of the Royal Dublin Society. Vol. 22 (N.S.), No. 19: The Chemical Constituents of Lichens found in Ireland—*Lecanora gangaleoides*, Part 2. By Dr. T. J. Nolan and Dr. J. Keane. Pp. 199–210. 1*s*. Vol. 22 (N.S.), No. 20: Further Experiments on Transpiration into a Saturated Atmosphere. By Prof. Henry H. Dixon and J. S. Barlee. Pp. 211–222 + plate 5. 1*s*. 6*d*. Punjab Irrigation Research Institute. Report for the Year ending April 1938. Pp. vii + 156 + 84 plates. Research Publication, Vol. 2, No. 23: An Investigation of the Inter-Relation of Silt Indices and Discharge Elements for some Regime Channels in the Punjab. By Dr. N. K Bose and Dr. J. K. Malhotra. Pp. vi + 70 + 11 plates. (Lahore: Punjab Irrigation Research Institute.) 1.10 rupees; 2*s*. 5*d*. [123 and economics; (2) a great demand for short courses of about four lectures in places where men are stationed for two months or more; and (3) an appreciable demand for classes in French and German. A scheme worked out by the staff of an evacuated school for men billeted in their area showed that the demands were in many cases more 'practical' than those described above. French and German were asked for by the majority, and next in order of popularity came shorthand and typewriting. Other requests were for mechanics, military geography and building construction. According to a reply from another battalion, contemporary history and current affairs were greatly in demand, while other topics that were repeatedly asked for included first-aid, physiology, psychology, criminology, police law and practice, etc. From the foregoing it may be seen that the provision of *ad hoc* courses would be insufficient and unsuitable for all the varied interests. The facilities provided should coincide with local demands so far as possible. Lecturers on scientific topics would be able to offer their contributions according to the regional demands.

The men in anti-aircraft and coastal defence units deserve particular attention. Many of them are desperately in need of educational facilities to relieve their long hours of monotony. It is heartening to find in Mr. Stanley's statement that for these units a more ambitious scheme involving continuous forms of education is under consideration. An official of experience in adult education is being seconded from the Board of Education and, in association with a military representative and an experienced welfare worker, is to prepare a scheme whereby educational and recreational facilities are to be developed side by side.

Considerable evidence is available to indicate the great importance of adequate library facilities to ensure the success of such a scheme, while the use of itinerant and peripatetic tutors would do much to encourage studies under adverse conditions.

The responsibilities devolving upon scientific workers to collaborate in any prepared schemes of continuous education would, if possible, be even greater than in peace-time. Astronomy, meteorology, horticulture and agriculture are subjects that have frequently been asked for by men in these isolated units, while other sciences would undoubtedly be in demand.

The supply of teaching personnel to satisfy these varying demands should not present any considerable difficulty; lecturers and tutors of all types would be more than ready to take an active part in any schemes of education that are prepared. The staffs of universities and university colleges have already expressed their willingness to contribute to the general scheme. It is to be expected that others who are interested in adult education would be available. A plea should also be made that the young school teachers who are already serving in the Forces should be made use of. Many of these teachers who have been conscripted would be glad to avail themselves of opportunities for getting practice in teaching; their adaptation to the elastic conditions that must inevitably arise should do much to increase their efficiency on their return to civil life.

Education in the Armed Forces is unquestionably a subject that is fraught with considerable difficulties. The one aim that should be constantly before our eyes is to discover the shortest method of bringing the War to a successful conclusion, and it is clearly recognized that in no circumstances must anything be allowed to interfere with military training or efficiency. But the contribution that mental alertness can make to military efficiency must also be fully grasped; its value to the peace and after is paramount. It is time, therefore, that the provisions made for educational services should be clearly stated, and a clear-cut policy adopted. To that end it is important that the schemes proposed by the Central Advisory Council should be carefully scrutinized. It is doubtful whether these schemes can be fully implemented until control is given to someone possessing the position, authority and drive enjoyed by Lord Gorell at the end of the War of 1914–18 in his capacity as head of the Army Educational Corps.

The establishment of a strong central organization would provide means whereby negotiations could be carried out with academic and professional bodies for the due recognition of the educational work done by men and women in the Forces. It could also arrange for the collection and distribution of books, films and equipment, etc. This central body would be able to co-ordinate the activities of the Central Advisory Council and the regional committees by the appointment of education officers in each battalion. The appointment of education officers would carry numerous advantages. They would be able to provide relevant information about the kind of educational services required in their particular units; they could give individual attention to all the educational problems confronting men drawn from primary and secondary schools, training colleges and universities. Thirdly, they would accompany their battalions when transferred from one district to another in Britain, and perhaps overseas.

It is important that educational facilities should not be limited to men and women in Great Britain. The extreme value of educational services in helping thousands of wounded soldiers towards recovery was strongly indicated by the Director-General of Army Medical Services in 1914–18. The acceleration of recovery through the awakening of mental interest should be a commendable feature at the present time. There has already been a steady demand overseas for lessons in the French language, the provision of which has performed useful service in consolidating Anglo-French relations. The success achieved by the introduction of these classes should be sufficient encouragement for the development and extension of educational services overseas.

ASPECTS OF THEORETICAL PHYSICS

(1) Lehrbuch der theoretischen Physik

Von Prof. Dr. Georg Joos. Dritte Auflage. Pp. xviii + 704. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1939.) 24 gold marks.

(2) Lectures on Quantum Mechanics

By Prof. M. Raziuddin Siddiqi. Vol. 1. Pp. xi + 293. (Hyderabad: Osmania University, 1938.) 6 rupees; 8*s*. 6*d*. net.

(3) Atombau und Spektrallinien

Von Prof. Arnold Sommerfeld. Band 2. Zweite umgearbeitete und erweiterte Auflage des "Wellenmechanischen Ergänzungsbandes". Pp. xi + 820. (Braunschweig: Friedr. Vieweg und Sohn, 1939.) 35 gold marks.

(4) La Chimie Mathématique

Vol. 1: Théorie Nouvelle de la Mécanique Statistique. Par Prof. Th. De Donder. Pp. 83. (Paris: Gauthier-Villars et Cie., 1938.) 40 francs.

(5) Hand- und Jahrbuch der chemischen Physik

Herausgegeben von A. Eucken und K. L. Wolf. Band 3, Teil 2, Abschnitt 3–4: Die Boltzmannsche Statistik und ihre Modifikation durch die Quantentheorie, von A. Sommerfeld und L. Waldmann; Freie Weglänge und Transporterscheinungen in Gasen, von Karl F. Herzfeld. Pp. x + 276. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1939.) 28.80 gold marks.

IF mathematical physics can justly be considered as the prototype of international science, as a language understandable to all, independent of nation and race, the present volumes not only testify to this fact, but also at the same time to the opposite statement: that differences of personality are inextinguishable and apparent even in the presentation of the most objective of sciences.

The first two books are text-books intended for the use of teachers and students. (1) Joos' work is a remarkable attempt to compress the whole of mathematical physics, up to the most modern branches, into one single volume. The success of this attempt (in Germany) is proved by the fact that three editions have been published in a few (seven) years. I have read sections of all chapters, starting with the excellent introduction on mathematical methods of physics, passing over classical mechanics, relativity, electrodynamics, thermodynamics, to the modern parts which deal with statistical mechanics, structure of atoms and molecules, quantum and wave mechanics, and ending with nuclear physics—and everything is equally well presented, clear, short and interesting. It is an admirable book, which can be warmly recommended to all who can read German fluently. Numerous examples, the solutions of which are contained in an appendix, will be very useful for the beginner.

(2) The second volume, by Siddiqi, published in Hyderabad, India, is of about the same apparent size, but covers only a narrow field, quantum mechanics. The size is in fact deceptive as the number of pages, 287, is very much smaller than that of Joos' book, 704, and the print more open; the weight of the two volumes is in the ratio 1 : 2. I should have liked to praise this book also very highly, but I have to refrain as I could not help recognizing too many features of my own lectures in Siddiqi's work. In fact, the author was among my students in Göttingen and went later to Leipzig, where he attended Heisenberg's lectures. Since Heisenberg and I had only just parted after some years of collaboration when he was my assistant, there is little wonder that his lectures were rather similar to my own.

This origin of Siddiqi's book, which can be traced even to details of notation, is partly revealed by the author as he has dedicated it to Heisenberg. There are, of course, some new sections, short references to the neutron and positron which were discovered more recently, to nuclear physics, and an outline of Dirac's theory of the electron. But as a whole, it is exactly the kind of presentation I would myself give if I ever have time enough to publish my lectures. Therefore I must frankly declare it a very good book, as regards selection of subjects, mathematical treatment, physical interpretation. As one example I wish to mention the derivation of the uncertainty principle, expressed by the formula $\Delta p . \Delta q \geqslant h/4\pi$, as given by Siddiqi in §10.6, in comparison, for example, with Sommerfeld's treatment in iii, §6, of his book (reviewed below); both are, of course, based on a well-known paper of Schrödinger (*Preuss. Akad.*, 1936), but the form of the proof given by Siddiqi, which uses the operator calculus, seems to me preferable because of its clearness. (This proof is also published in an appendix of my book "Atomic Physics".)

(3) The most important work among these five volumes is that of Sommerfeld, which reveals in every line the strong scientific personality of its author. The original work, now vol. 1 of the whole, appeared just before the discovery of wave mechanics, and Sommerfeld wrote his "Ergänzungsband" after this event as a short appendix to the main volume. But it soon became evident that this did not do justice to the importance of the new theory. Twelve years passed before Sommerfeld published this second volume, twelve years of incessant labour and continual improvement. The book has become a masterpiece indeed. The style is of the same simplicity and clearness as that of the original volume. The reader will never be puzzled by remarks like "it can easily be shown that . . ." which, in other books, indicate the presence of a particularly intricate difficulty and cost the serious student more time than the rest of the book.

Sommerfeld's work is a kind of codification of a considerable part of quantum mechanics, collecting results scattered over the literature of all nations and uniting them into a structure of great beauty. There are a great many sections containing Sommerfeld's original work, and that of his pupils. An important feature seems to me the careful derivation of normalization factors of eigen-functions, not only for discrete energy levels, but also for the continuous spectrum. These are used in a thorough study of the photo-electric effect (Chap. vi) and continuous X-ray spectra (Chap. vii). Where other books stop short because of increasing analytical complications, Sommerfeld just starts full swing, and it does not look any more involved. The Dirac electron is introduced at an early stage (Chap. iv) and used whenever spin effects are important. The treatment of the spin is a particularly fascinating feature; Sommerfeld does not use the spinor calculus generally adopted, in which the operators are 4×4 matrices with respect to the spin variable, but represents the spin properties with the help of a non-commutative algebra of sixteen units, which are formed by all independent products of four anti-commuting quantities γ_1, γ_2, γ_3, γ_4. His method of reduction of spin equations to ordinary equations, with help of null divisors (*Nullteiler*), is very powerful and simpler than the usual matrix calculus; and the relativity invariance of the equations can be shown in a most direct fashion. It is very interesting that this point of view has been recently adopted in a paper by N. Kemmer on meson theory (see *Proc. Roy. Soc.*, Nov. 1939), in which he shows that the particle aspect is better expressed by an abstract algebra, the wave aspect by a special matrix representation, both in the case of the electron and in that of the meson.

At the end of Sommerfeld's book there are several appendixes of a more mathematical character. For although the book itself contains formidable mathematics enough, it must be stressed that there is no sentence in which the physical idea is neglected or forgotten. It is a book on physics—mathematical physics, if you like—but not on 'applied' mathematics. But it demonstrates the great power of the mathematical method in describing natural laws. There is no other work which gives so full an account of the victorious path of modern theory. I hope that an English edition will be published.

(4) The next book of the collection is of the very opposite character. De Donder's new statistical mechanics is rather mathematical and formal. It can be read only by those who have a fair knowledge of the subject from other sources. The uninitiated reader would stumble over definitions the meaning of which must appear mysterious, and wonder about theorems stating results of no evident physical importance. I am myself not mathematically minded enough to appreciate the finesses of the procedure. So far as I understand it, the idea is to define all observable averages of a statistical ensemble by two kinds of derivatives, one with respect to phase volume (in the sense of Gibbs's micro-canonical ensemble), and one with respect to the number of particles (treated as a continuous variable). It is then possible to avoid all further references to ordinary counting and averaging, and to proceed quite formally.

I must confess that I was not able to follow the abstract argument. If, for example, the Bose and the Fermi statistics are derived from a general formula containing a quantity $\Delta\omega'$ (being apparently a finite increase of phase volume), by equating this $\Delta\omega'$ to $+1$ or -1 ("Faisons $\Delta\omega' = -1$; nous obtenons la loi de repartition qui caractérise la mécanique statistique de Fermi"), I feel uncomfortable and should like to ask why we are doing so. This non-physical attitude is characteristic of this book; but mathematicians may enjoy De Donder's rigorous treatment.

(5) The last volume brings us back to normal physics. It contains two articles treating statistical thermodynamics of gases, the first one in the case of equilibrium, the second one for stationary processes. Both are readable and in general up to date. The article of Sommerfeld and Waldmann gives a good account of classical and quantum statistics; it leads up to the condensation phenomenon due to van der Waals' forces, which are treated much in the traditional way, as the article was apparently sent to press a short time before the new powerful method of J. E. Mayer (*J. Chem. Phys.*, 5, 67, 74, 1937) was published. Herzfeld's article contains not only the usual considerations about transport phenomena in gases, but discusses also molecular rays, the modern methods of Chapman and Enskog, Knudsen's investigations of rarified gases, and many other questions. MAX BORN.

FRUIT PRODUCTION AND PRESERVATION

(1) The Fundamentals of Fruit Production
By Prof. Victor Ray Gardner, Frederick Charles Bradford and Henry Daggett Hooker, Jr. (McGraw-Hill Publications in the Agricultural Sciences.) Second edition. Pp. xvi + 788. (New York and London: McGraw-Hill Book Co., Inc., 1939.) 30*s*.

(2) Commercial Fruit and Vegetable Products
A Textbook for Student, Investigator and Manufacturer. By Prof. W. V. Cruess. (McGraw-Hill Publications in the Agricultural Sciences.) Second edition. Pp. x + 798. (New York and London: McGraw-Hill Book Co., Inc., 1938.) 36*s*.

FOOD production and preservation are subjects which concern everyone to-day. To its furtherance science has contributed from all their fields, and no side of food production has benefited more from scientific research than that of pomology. Every stage of production from the propagation of the young tree and the breeding and selection of new varieties to the marketing of the fresh fruit or the preserved article has received intensive study. A subject so wide is difficult to present in its entirety even in two volumes as large as those under review, and any authors attempting the task of collating and condensing the mass of literature must almost inevitably omit much which to other workers will seem of prime importance.

Taken together, these two books provide an almost complete encyclopædia of the application of science to fruit production, omitting only, in the case of the first book, the aspect of pest and disease control. Both are alike in that they approach their subject from the scientific point of view rather than the empirical and practical. In the first, cultural practices are considered only in so far as they modify the relation of the plant to the complex of the environment, and it is this latter which receives first attention. In the second, while manufacturing technique is the dominating theme, the dependence of the technical processes on fundamental principles and the results of research is stressed throughout.

Unfortunately, to the student in Great Britain, both suffer from the same defect, the failure to present adequately the contributions of research workers in this country. In this respect the book by Prof. Gardner and his co-workers is open to the greater criticism. It is surprising, for example, to find no mention, in the otherwise admirable account of the seasonal changes in carbohydrates and nitrogenous substances in the apple tree, of the now classic series of investigations by Smyth, Karmarkar, Kench and others at Long Ashton Research Station. Again, a discussion of the root systems of fruit trees is very incomplete without reference to the work of Rogers at East Malling. Many other such instances might be given.

The book is divided into seven sections, dealing respectively with water relations, nutrition, temperature relations, pruning, fruit setting, propagation, and geographical influences on fruit production. The authors freely admit that comparatively little that is original is presented; their aim has rather been to survey the field of research and show how the results of scientific investigation may be applied to the problems of practical growing. It is, however, to be regretted that this second edition of a book so well known should have been prepared almost entirely by additions to the old text rather than by a thorough rewriting. In some sections this is of no consequence, as recent work has only enlarged or extended previous knowledge. The sections on pruning and propagation, however, lose greatly by the failure of the authors to re-orientate the outlook in the light of the new hormone concept of plant growth and regeneration. The revolution which this concept has brought about in physiological ideas is so great that lack of any mention is a serious omission. Nevertheless, students of pomology owe a debt of gratitude to the authors for collating so much material from the original sources and presenting it in a digested and readable form.

Prof. Cruess takes up the story at the point where the other authors leave it. His book is an exhaustive survey of the principles and practice of fruit and vegetable preservation from the commercial point of view. It is designed as a university or college text-book for courses in food technology, but will be of equal value to the scientifically minded manufacturer. As would be expected in an American book, chief attention is given to the technique of canning, which occupies about one third of the whole volume, but every product manufactured from fruit and vegetables receives adequate consideration, from dried fruits to pickles and wines. For the English student insufficient discussion is given to the manufacture of cider and perry, but this is easily understandable in a book written for American conditions where these products are of very minor importance.

Three useful and interesting chapters at the end deal with vitamins, plant pigments and the enzymes of fruit and vegetables. Prof. Cruess follows the latest American practice in re-naming vitamin B_2, vitamin G, and preserves a nice neutrality on the controversy concerning its identity with lactoflavine. The treatment of the anthocyanins is somewhat cursory in view of their importance in the appearance of canned and other products, and some review of the work of Scott-Moncreiff on the chemistry of these compounds would have added interest. The book is, however, not intended as a biochemical treatise, and it succeeds admirably in its main function of reviewing the most modern technique in food preservation.

R. H. STOUGHTON.

HUYGENS' PRINCIPLE

The Mathematical Theory of Huygens' Principle
By Prof. Bevan B. Baker and Prof. E. T. Copson. Pp. vii+156. (Oxford: Clarendon Press; London: Oxford University Press, 1939.) 12*s*. 6*d*. net.

THERE are several parts of the science of physics which appear very simple when expounded briefly in elementary text-books, but nevertheless present great difficulties when examined more carefully. A good example of this is furnished by Huygens' principle, which in its original form discusses the propagation of light by asserting that the wave front is the envelope of secondary waves whose centres are themselves on a previous wave front. The first difficulty in this elegant geometrical construction is that it gives not only the actual wave propagated forwards, but also another propagated backwards, which does not really exist. To the simple principle Huygens therefore added the special assumption that only one sheet of the envelope, namely that propagated forwards, was to be considered. The next difficulty is to explain diffraction. To do so, Fresnel replaced Huygens' isolated spherical waves by purely periodic trains of spherical waves, and made use of the principle of interference. He had to restrict his treatment to the case of small wave-lengths, and also had to make two additional assumptions concerning the relations of the amplitudes and phases of the secondary waves to those of the primary. The necessity for these two additional assumptions, which appear to be of an arbitrary character, has led some to consider Fresnel's theory as merely a convenient device for calculation without any sound physical basis. In any case, the principle so far takes no account of the phenomenon of polarization, although this was discovered by Huygens himself. In fact we may say that what was put forward as a theory of optics cannot, in anything like its original form, be legitimately applied to that branch of physics, though it may apply to acoustics. The necessity for a careful re-examination of the subject is now apparent. Unfortunately, this seems possible only on an analytical basis, with rather complicated mathematics; the elementary geometrical treatment appears to fail to give the results required, unless it is supplemented by special assumptions.

This re-examination of Huygens' principle was part of a much larger programme, covering the whole field of the partial differential equations of mathematical physics, which was the subject of a course of lectures by Prof. E. T. Whittaker sixteen years ago, and was to have been treated in a comprehensive text-book by his pupil, now Prof. B. B. Baker. Unfortunately, ill-health and pressure of other duties intervened, and Prof. Baker, in collaboration with Prof. E. T. Copson, intends to replace the projected treatise by a series of monographs, of which this is the first. The reader is assumed to have a knowledge of pure and applied mathematics roughly equal to what is possessed by an honours student of mathematics who has completed the compulsory parts of his degree course, and is about to enter upon some specialized study. The book deals with the subject in connexion with the general theory of the solutions of the partial differential equations involved, with some of the simpler diffraction problems as examples illustrating that theory.

The book contains four chapters. The first deals with Huygens' principle in what may be called its acoustical form. The theorems of Poisson and Helmholtz are given, but are shown to be included in that of Kirchhoff, which is the proper analytical formulation of the 'acoustical' principle. The two-dimensional analogue is due to Volterra. Marcel Riesz treated the case of cylindrical waves in an elegant manner, using the theory of the analytical continuation of a function of a complex variable.

The second chapter gives Kirchhoff's theory of diffraction, and the criticisms of it by Poincaré and Kottler. This theory, in addition to being difficult to apply to special problems, seems to involve conditions not intended by its author.

The third chapter takes account of polarization, and gives the three methods due to Kirchhoff, Larmor-Tedone, and Kottler. It is shown that the first and second fail, but the third appears to have overcome the difficulty of defining "blackness".

The fourth chapter gives Sommerfeld's and Voigt's methods of solving certain diffraction problems, chiefly two-dimensional, such as diffraction by a half-plane. These give results agreeing fairly well with experiment, but a rigorous theory, taking into account the properties of the material of the screen, is still lacking.

It is unfortunate that the book did not appear about the time of the original lectures. At present mathematical physicists are busy with the rapid developments of modern physics, and older problems are likely to be neglected.

H. T. H. PIAGGIO.

ENZYMES FROM MANY ASPECTS

Ergebnisse der Enzymforschung
Herausgegeben von F. F. Nord und R. Weidenhagen. Band 8. Pp. x+324. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1939.) 28 gold marks.

THE early volumes of this annual compilation dealt with the individual enzymes, their properties and mode of action: attention is now turning to the role of enzymes in normal and pathological metabolism.

The opening article by R. W. G. Wyckoff of Pearl River, New York, deals with the subject of purified viruses, those agents of transmissible disease which are smaller than demonstrable micro-organisms. In connexion with them the question has been raised whether they are living agents or a transitional form intermediate between animate and inanimate matter. Their study may be an approach to the meaning of the term 'alive'.

The experimental problem is to get them in concentrated and purified form. More than one hundred virus diseases are now known, each with its characteristic causative agent in which a protein carries the virus. The proteins are large aggregates, and we are beginning to find out something about their size and shape by the application of a number of ingenious physical methods.

Attention is further being turned to the discovery of macromolecules in healthy tissues; several have been found in plants—they are pigmented, sediment at about the same rate, and may be macromolecular chlorophylls. They are smaller than the smallest virus proteins.

The mechanism of a still very obscure reaction, that of symbiotic nitrogen fixation, is discussed by P. W. Wilson of Madison, Wisconsin. A forty-page summary emphasizes that what is now required are experimental data rather than interpretations: the difficulty is to devise crucial experiments.

Each enzyme has in the laboratory an optimum *p*H concentration for maximum activity, but it is uncertain whether the same applies to its behaviour in the tissues. H. J. Vonk of Utrecht discusses this subject in relation to the digestive enzymes. As the various enzymes have different *p*H optima, the concentration in the intestine cannot be the best for any one of them but must be a compromise suitable more or less to all.

Enzymes are beginning to be sought for as an aid to clinical diagnosis. A rather lengthy essay by R. Ammon and E. Chytrek of Breslau summarizes present knowledge.

R. J. Dubos of New York describes the enzymatic analysis of the antigenic structure of pneumococci. It is known that the capsular polysaccharides of the different types are of paramount importance in conditioning the serological specificity and virulence of these organisms. When virulent pneumococci are treated with enzymes which destroy their capsule, they lose also the property to agglutinate in specific antiserum.

There are in all eleven articles, but enough has been said to indicate the variety of subject. The contributions are, as usual, international in source, and it is interesting to note two from Indian laboratories, though the work of Miss Scott Moncrieff was done at Cambridge.

E. F. A.

THE DRIFT OF THE ICE-BREAKER *SEDOV*

By Prof. N. N. Zubov

Attempts have been made by many expeditions to penetrate to the central part of the Arctic Ocean. A few have even succeeded in reaching the North Pole itself. After several unsuccessful attempts, the American explorer Robert Peary, on April 6, 1909, reached the North Pole on sledges drawn by dogs and remained there for some thirty hours. On May 9, 1926, the American aviator, Admiral Richard Byrd, flew to the Pole by aeroplane and describing a circle in the air, returned safely to Spitsbergen, the starting point of the flight. In the same year, the Norwegian explorer Amundsen crossed the Arctic Ocean from Spitsbergen to Alaska in a dirigible, flying over the North Pole on May 12. On May 24, 1928, the Italian expedition of General Nobile also succeeded in reaching the North Pole in a dirigible, which circled over it; but the expedition met with disaster on the return flight and some of the members perished.

Concerted attempts to reach the North Pole were made by Soviet explorers in 1937, in which year nine Soviet aeroplanes flew over the Pole. While the North Polar Station on the drifting icefloe was being set up; there were present at the Pole four heavy aeroplanes and thirty-three Soviet polar explorers. During those days five aeroplanes, piloted by Molokov, Golovin, Vodopianov, Alexeyev and Mazuruk, flew over the Pole. On June 18, 1937, Chkalov's machine passed over the Pole on his flight from Moscow to the United States. On July 13, 1937—following the same route—Gromov flew his machine over the North Pole; on August 13, Levanevsky flew over the North Pole on his way to America. Levanevsky was afterwards lost and during the search for his machine, Vodopianov flew over the Pole on October 7, 1937, and Moshkovsky on April 4, 1938.

Forerunners of the *Sedov*

Only three expeditions have drifted with the ice in the Arctic: Nansen's expedition of 1893–96 on the *Fram*, Papanin's North Polar expedition on the drifting icefloe of 1937–38, and the expedition of the Soviet polar explorers on the ice-breaker *Sedov* (Nature, 143, 837; 1939).

Nansen's expedition did not reach the North Pole. During her drift the *Fram* only reached lat. 85° 56′ N. Yet it was Nansen who, in a scientific sense, literally discovered the Arctic Ocean. Prior to the drift of the *Fram* very little indeed was known about this ocean. Nansen himself did not expect to find depths exceeding 500 m. (1,640 ft.) and consequently did not take with him the necessary equipment for sounding great depths.

From Nansen's expedition it was learned that the Arctic Ocean was a sea having depths of more than 3,000 m. (9,843 ft.). The warm Atlantic waters—a branch of the Gulf Stream—were shown to penetrate as a deep current far into the central part of the Arctic Ocean. Nansen's observations revealed the primary conditions of the movement of the ice in this basin. Lastly, Nansen also studied the principal conditions governing the formation, development and disintegration of sea ice. There is not an aspect of oceanography and geophysics relating to the Arctic Ocean to which Nansen's expedition did not make important discoveries.

On May 21, 1937, with the help of four heavy aeroplanes, the Pananin expedition was landed on the ice. On a big icefield the Soviet polar explorers set up a well-equipped polar observatory. On June 6 the organization of the North Polar Station was completed. The aeroplanes flew back to the mainland, leaving Papanin, Krenkel, Shirshov and Fedorov on the ice. They remained on the icefloe for 274 days. During this period the icefield of the Papanin expedition was carried from the North Pole to the east coast of Greenland where, at lat. 70° 54′ N. and long. 19° 48′ W., the drifting expedition was taken off by the ice-breakers *Taimyr* and *Murman*.

The men of the expedition on the drifting icefloe measured all depths along the entire course of their drift from the North Pole to the coast of Greenland. They revealed the movement of the ice and sea current under the ice which had escaped Nansen's attention. They refuted Nansen's theory that no life existed in the central part of the Arctic Ocean. They carried out valuable observations on terrestrial magnetism. The meteorological observations of the Papanin expedition not only facilitated the organization of the trans-Arctic flights of Chkalov and Gromov, but also contributed to our knowledge of the structure of the atmosphere and the processes determining the weather in the central part of the Arctic.

START OF THE *Sedov* DRIFT

Contrary to the drifts of the *Fram* and the North Polar Expedition on the drifting icefloe, the drift of the *Sedov* was not deliberately planned. With the ice-breakers *Sadko* and *Malygin*, on October 23, 1937, the *Sedov* was caught in the ice in the Laptev Sea at lat. 75° 19′ N. and long. 132° 25′ E. On August 28, 1938, these ice-breakers were at lat. 83° 06′ N., long. 138° 24′ E. On that day the ice-breaker *Yermak* extricated the *Sadko* and *Malygin* from the ice and brought them into clear water. The *Sedov*, however, could not be released owing to the fact that during her imprisonment in the ice she had sustained some damage to her steering gear.

Fifteen volunteers, headed by Captain Badygin, remained on the *Sedov*; and from that time the vessel continued her remarkable drift in the most inaccessible part of the Arctic Ocean, where no other vessel had ever drifted before and no aeroplane had flown.

Several circumstances make the drift of the *Sedov* of exceptional interest. First, the drift of the ice-breaker began at a time when the North Polar Expedition on the drifting icefloe was still making observations. Thus, uninterrupted observations of the central parts of the Arctic Ocean were being conducted. Secondly, soon after the commencement of the drift of the *Sedov* and also in the Laptev Sea but in the south-western part, there began the drift of several vessels headed by the ice-breaker *Lenin*. These vessels had been carried from Khatanga Bay. The drift of the ice-breaker *Lenin* ended on August 7, 1938, when, with the entire caravan of ships, she was extricated from the ice by the *Krassin*. Thus, for nine months two caravans of ships drifted simultaneously at some distance from each other, one in the south-western part of the Laptev Sea, the other in the north-eastern part of the same sea, and in the region to the north of the New Siberian Islands.

A comparison of these drifts has yielded noteworthy results. Differing from each other in details, these drifts at the same time reveal extraordinary similarity, a fact which goes to show that they were conditioned by the same causes: the prevailing winds and constant currents.

Thirdly, soon after the commencement of her drift, the *Sedov* found herself in the region where the drift of Nansen's *Fram* started.

A comparison of the subsequent courses of the drifts of the *Fram* and the *Sedov* is of exceptional interest, because the former took place in climatic conditions differing considerably from those of the present day. At first the *Sedov* drifted directly northwards. In a month, under the influence of west winds the ice-breaker turned eastwards, and early in January, 1938, reached the most easterly point of her course—lat. 78° 25′ N. and long. 153° 26′ E. From that time the *Sedov* began slowly to move westwards, at the same time going more and more to the north. She continued this north-westerly direction, and on March 22, 1939, reached lat. 86° 34·7′ N. and long. 108° 50′ E. Later, the drift began gradually to incline to the south-west. From May 17 until July 27, 1939, the courses of the *Sedov* and the *Fram* overlap, as it were, but afterwards the *Sedov* again commenced to go rapidly to the north, and on August 29, 1939, reached the northernmost point of her drift, lat. 86° 39·5′ N., long. 47° 55′ E. After that the *Sedov* again descended to the south, crossing the *Fram's* course, and along a line lying between the drifts of the expedition on the drifting icefloe and that of the *Fram*, made for the broad strait dividing Greenland from Spitsbergen. From December 1, 1939, the *Sedov* was finally drawn into the drift of the ice moving from the Arctic Basin to the Greenland Sea; with gradually increasing speed the ice-breaker drifted almost due south. On January 1, 1940, she had already reached lat. 81° 15·4′ N., long. 4° 16′ E. She was afterwards extricated from the ice by the ice-breaker, *Joseph Stalin*. Her crew was taken off the vessel on January 13, and on January 29, 1940, the *Sedov* arrived in Murmansk.

END OF A LEGEND

One achievement of the *Sedov* is the final explosion of the Sannikov Land legend. In 1811 Jacob Sannikov purported to have sighted from the northern coast of Kotelny Island a high land which he attempted to reach by crossing the ice; he was prevented from doing so by a big polynia (an expanse of clear water in the icefield). According to Sannikov, there remained only another 25 kilometres (15½ miles) for him to cross in order to reach this land. Doubts as to the existence of this supposed land have, however, been held by many for several decades.

The *Sedov*, during the period of her drift, twice crossed the region of the supposed land: once from west to east, approximately at the 78th parallel, and the second time from the south-east to the north-west. Later, the air expedition of Alexeyev passed over the region approximately in a meridianal direction. The flights were from the northern extremity of Kotelny Island to the drifting caravan of vessels, the *Sadko*, *Sedov* and *Malygin*, and were made at a time when visibility was excellent.

Through this same region also passed the ice-breakers *Yermak* and *Joseph Stalin* on their way to meet the drifting vessels. Yet neither ice-breaker saw any sign of 'Sannikov Land'.

Boundary of the Laptev Sea

From the point of view of physical geography, the Laptev Sea is not a sea but only a gulf of the Arctic Ocean. The northern boundary of this sea is conditional, having been fixed by the Soviet Government as the arc of the great circle connecting Cape Molotov (the northern point of Severnaya Zemlya) with the point at which the meridian crosses the northern point of Kotalny Island (long. 139° E.) and the edge of the continental shelf. The drift of the *Sedov* from the beginning up to lat. 79° 37′ N., long. 149° 58′ E. proceeded along the continental shelf. The depths did not exceed 200 m. However, at lat. 79° 52′ N., long. 148° 02′ E., the *Sedov* found herself over depths considerably exceeding 3,000 m., that is, at depths characteristic of the deep bed of the central part of the Arctic Ocean.

The region lying to the north of the New Siberian Islands has been thoroughly sounded. From a comparison of these soundings, it appears most probable that the continental shelf at the Kotelny Island meridian (long. 139° E.) ends at lat. 78° 30′ N. This must be considered as the north-eastern point of the Laptev Sea.

As was found in the region of the New Siberian Islands, the continental shelf stretches farther north than was supposed, and the continental slope is much more gradual. It occupies 2° of latitude and has a gradient of not more than 1.

To the north of Franz Josef Land great depths were unexpectedly discovered. At lat. 86° 26·6′ N., and long. 39° 25′ E. the expedition failed to find bottom at 5,180 m.

Extremely interesting are the soundings obtained by the *Sedov* in the latter stages of her drift—at the entrance to the Greenland Sea. Nansen surmised that between the north-eastern extremity of Greenland and the north-western extremity of Spitsbergen was a submarine ridge separating the great depths of the Arctic Ocean from the great depths of the Greenland Sea. This ridge came to be known as Nansen's submarine ridge. Its eastern part was studied in 1935 by the *Sadko* expedition, and the western part by the Papanin North Polar Expedition on the drifting icefloe. The *Sedov* crossed Nansen's submarine ridge in its middle part, at lat. 81° 34′ N., long. 4° 40′ E., and registered a depth of 1,500 m., thus confirming the existence of this ridge.

The Russian Drifts.

——— actual drift, ------- theoretical drift without account of constant currents. —·—·— theoretical drift with account of constant currents.

Changes in the Thermal Balance

In addition to the sounding of depths, the *Sedov* crew carried out meteorological, hydrological magnetic and gravimetrical observations along the same lines as the members of the North Polar Expedition on the drifting icefloe. The observations of the *Sedov* crew confirmed what has already been recorded by the Papanin expedition and by Nansen: on the whole course of their drift they discovered at intermediate depths warm waters of Atlantic origin.

The fact that the lines of the drifts of the *Fram* and the *Sedov* crossed in several places has made it possible to determine the changes in the thermal balance of the Arctic Basin during the last forty-five years.

The *Sedov* remained twice as long beyond the 85th parallel as the North Polar Expedition on the drifting icefloe, and two and a half times as long as the *Fram*, though the drift of the latter lasted nearly three years. The *Sedov* began her drift considerably farther south than the *Fram*, and at the end of it she descended to more southerly latitudes than Nansen's vessel, yet the *Sedov's* drift lasted only 26½ months. This indicates that the speed of the *Sedov's* drift was considerably greater than that of the *Fram*.

The increased movement of ice from the Arctic Basin into the Greenland Sea is accompanied by an increase in the flow of warm Atlantic waters into the polar basin, a reduction in the volume of ice in seas bordering on the Arctic, a decrease in the thickness of polar ice and size of glaciers, and also by a rise in the winter temperatures of the air. All these phenomena are characteristic of the warmer temperatures we are now observing in the Arctic.

Notwithstanding the fact that the line of the *Sedov's* drift was considerably more northerly than the line of the *Fram's* drift, the winter months in the Arctic in Nansen's time were several degrees colder than at the present time. The lowest temperature of the air (—44·1°) was registered by the *Sedov's* crew on March 10, 1939, at lat. 86° 23′ N., long. 110° 20′ E. The lowest temperature during the drift of the *Fram* (—52°) was registered on January 15, 1896, approximately at lat. 84° 55′ N., long. 41° E., that is, appreciably more south-west than the spot where the *Sedov's* lowest temperature was registered and where, as a rule, it is warmer.

The thickness of level ice according to the measurements of the *Sedov's* crew was not more than 218 cm. (7 ft. 2 in.). Nansen's expedition encountered ice 365 cm. in thickness. Analysis has shown that the lesser thickness of the ice in the region of the *Sedov's* drift was due not so much to the rise of the winter temperatures of the air as to the melting of the ice in recent years in summer time.

BELT OF HUMMOCKS

In the light of the observations made by the *Sedov's* crew, interest is attached to questions concerning the maximum thickness of the ice. The members of the North Polar Expedition on the drifting icefloe never encountered ice of a greater thickness than 218 cm. That being the case, where was the icefield on which the expedition set up its observation station formed, and how did it reach the North Pole ? We know that this icefield was more than 3 m. thick. Why was the *Sedov*, which on March 22, 1939, was 180 km. (97·12 nautical miles) farther to the north than the *Fram* and afterwards, like the *Fram*, turned westwards, unable to penetrate to the 87th parallel ? The highest latitude reached by the *Fram* was 85° 55·5′ ; the highest latitude reached by the *Sedov* was 86° 39·5′. The northernmost point reached by Nansen during his sledge journey to the North Pole was lat. 86° 14′ ; lastly, in 1900 Cagni in the same region reached lat. 86° 34′ N. Both Nansen and Cagni were prevented from going farther north by impenetrable hummocky ice.

These data should be compared with the observations made by Alexeyev during his flights from Franz Josef Land to the North Pole and back. Alexeyev ascertained that from Rudolf Island up to lat. 82° 30′ N. lie hummocky fields of young ice dotted with icebergs. Higher, up to lat. 85° 30′ N., the size of the icefields increases, reaching 20 km. across. On these fields are level platforms suitable for the landing of aeroplanes. At the 84th parallel the thickness of the ice did not exceed 100–120 cm. Beyond 85° 30′ commenced an icefield of ice many years old, while up to the 86th parallel the icefields were small and hummocky, and the lanes between the icefields were filled with broken ice. In these places it was impossible to land aeroplanes. Farther north, particularly between 87° and 88° 30′, the icefields appeared more suitable for landing-places. The condition of the ice in the region of the North Polar Expedition on the drifting icefloe is already known.

From the foregoing, we see that between the North Pole and Franz Josef Land is situated a belt of hummocks of a peculiar character. This belt separates the younger ice, formed mainly on the continental shelf of Eurasia, from the thicker ice near the North Pole. It seems that this belt of hummocks which, in its time, had stopped the further advance to the north of Nansen and Cagni, is a permanent feature.

NANSEN'S LAWS

Four times a day the men on the *Sedov* transmitted by radio their position and meteorological observations. This made possible a comparison of the ice drift with the wind causing the drift. Such observations made near coasts are usually distorted by the nearness of land and shallows ; and so, for a theoretical study we are only able to use the data supplied by three drifts, those of the *Fram*, of the Papanin North Polar Expedition on the drifting icefloe (while it was in the central part of the Arctic Ocean) and of the *Sedov*.

Like all known drifts, the drift of the *Sedov* did not proceed in a straight line. The ice-breaker often turned back on her course, described zigzags and even loops. These changes of direction were caused by changes in the direction and velocity of the wind. In this connexion, very characteristic are the figure 8 described by the *Sedov* between October 2 and 26, and the zigzags between November 10 and 30, 1938, and the loop she made between January 3 and 17, 1939.

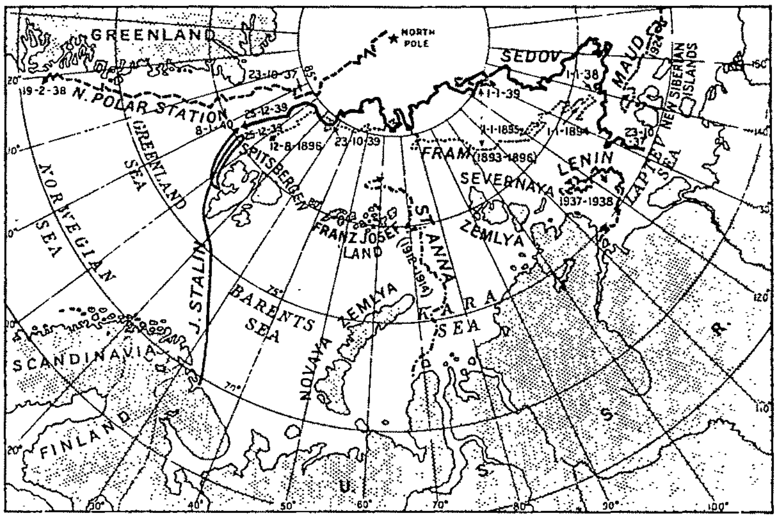
The only difference between the direction of the drift and the direction of the wind was that the drift was deflected 30°–40° to the right. Any deviation from this law can be attributed to the incompleteness of the *Sedov's* observations at my disposal.

The observations of the *Sedov* worked out by me show that in the region where the *Sedov* drifted between September 1, 1938, and February 1, 1939, the constant current was so weak that it might be said to have been absent. As a result, almost laboratory conditions prevailed for the study of the relations between wind and drift. Far removed from the distorting influence of land and constant currents, the wind drift was shown here practically in its pure form.

In this way it was possible to confirm yet again the exactness of the two simple laws of Nansen determining the behaviour of solid ice in the central part of the Arctic Basin. These laws are as follows :

(1) The speed of the wind drift is approximately one fiftieth of the velocity of the wind causing the drift.

(2) The drift of the ice is deflected from the direction of the wind by 30°–40° to the right owing to the influence of the deflecting force of the earth's rotation.



Drifts of the *Maud, St. Anna, Fram,* the ice-breakers *Lenin, Sedov* and Papanin's North Polar Expedition, and also the course of the ice-breaker *Joseph Stalin.*

Two Additional Laws

A study of the drift of the *Sedov* makes it possible to add to Nansen's two laws two other equally simple laws :

(3) The drift of the ice follows the isobars. The ice drifts along these lines in such a way that the region of high pressure is to the right of the direction of the drift, and the region of low pressure to the left.

(4) The drift of the ice takes place at a speed proportional to the gradient of atmospheric pressure, or in other words, inversely as the distance between the isobars.

The first of these additional laws is not difficult to deduce. In moderate and high latitudes the wind, due to friction against the surface of the earth and to the influence of the deflecting force of the earth's rotation, is directed approximately 30°–40° to the left of the corresponding isobar. The drift of the ice, according to the second of Nansen's laws, is deflected from the direction of the wind approximately by 30°–40° to the right. Combining the two, we arrive at the drift of the ice along the isobar.

The second additional law was arrived at thus In the absence of constant currents and the deflecting influence of land, the ice moves at a speed proportional to the velocity of the wind. The latter, in its turn, is proportional to the gradient of atmospheric pressure ; the closer the isobars are drawn on the synoptic chart for any given region, the stronger are the winds in that region. From this, supported by purely theoretical deductions, it was possible to judge from the synoptic chart not only the direction of the ice drift, but also its speed.

Theoretical calculations made on the basis of the new laws confirm the hypothesis that the ice moves clockwise around the so-called 'pole of inaccessibility'. Had the *Sedov* in January and February 1939 been somewhat more north than she actually was at that time, it is highly probable that she would have been drawn into this clockwise movement around the 'pole of inaccessibility' and would have been drifting now towards the northern coasts of America.

The new laws offer an explanation of the known drifts of vessels and buoys and also of such arctic phenomena as 'Peary's polynia' at the coast of Greenland, also the 'Great Siberian polynia' stretching with interruptions from the New Siberian Islands to the Chukotsk Sea. These polynias coincide with the lines of separation of the ice, or in other words, with the lines of the divergence of the isobars.

The movement of the ice along the isobars also explains why Amundsen's *Maud*, when entering the ice at Wrangel Island for the purpose of drifting across the North Pole, moved with the ice along the continental slope of the Asiatic coast, that is, along the parallel and not the meridian. It appears that the isobars in the vicinity of Wrangel Island both winter and summer stretch along the parallels. In order to drift with the ice to the North Pole it would be better to enter the ice in the region of the Beaufort Sea, whence, apparently, the icefield occupied by Papanin's North Polar Expedition was carried.

THEORETICAL DRIFT AND ACTUAL DRIFT

On the basis of the monthly charts of pressure, the theoretical drifts were plotted of Papanin's North Polar Expedition (May 21, 1937, to February 1, 1938), of the ice-breakers *Sedov* (November 1, 1937, to October 1, 1938) and *Lenin*. Afterwards, according to latitude and longitude, the actual drifts of these vessels were indicated on the chart. The similarity between the lines of the theoretical drifts and those of the actual drifts was noteworthy.

The actual drifts of the *Sedov* and of the *Lenin* came very near those calculated by theory. There was, however, considerable difference between the actual and theoretical drifts of Papanin's North Polar Expedition. In the first place, the theoretical drift of Papanin's Expedition came out to the coast of Greenland, and in the second place, it was shorter than the actual drift (if calculated by latitude) by 550 nautical miles. This difference is accounted for by the fact that in calculating the theoretical drifts, account was taken only of the influence of local winds, whereas the movement of the ice is conditioned not only by winds, but also by constant currents.

Naturally, in regions where the constant currents are weak, the influence of local winds on the speed and direction of the drift is paramount. With the approach to the Greenland Sea, the local winds, owing to the strong East Greenland current, have less and less influence on the icefields. The weak winds, the direction of which is contrary to that of the constant current, now only slow down or delay for a time the general drift to the south. This happened in the case of Papanin's North Polar Expedition, and also in the case of the *Sedov*.

The difference between the actual and theoretical drifts of the Papanin North Polar Expedition is also connected with the speed of the wind drift of mass icefields in the central Arctic. This is one fiftieth of the velocity of the wind causing the drift; but the speed of the drift of ice under the influence of wind is considerably increased if ahead of the ice, in the direction of the wind, is open sea. In this case, the speed of the drift may reach one tenth of the velocity of the wind or sometimes even more. Conditions such as these are created when north and west winds prevail in the region of the central Arctic adjoining the Greenland Sea, or in the Greenland Sea itself.

In this sea, along the east coast of Greenland right up to lat. 60° N., summer and winter there moves to the south an uninterrupted line of polar ice carried from the Arctic Basin by the East Greenland current. At the same time, to the north, along the west coasts of Scandinavia and Spitsbergen, flow warm Atlantic waters, which as a deep current later penetrate into the Arctic Basin. Owing to this, the eastern edge of the Greenland ice stretches approximately from Iceland through Jan Mayen Island to the north, up to the northwestern extremity of Spitsbergen. In the summer, the edge recedes to the west, and in the region situated to the north of Spitsbergen, in some years goes up to lat. 82° N. In winter-time, the edge of the ice in the Greenland Sea moves somewhat to the east and at Spitsbergen descends to lat. 80° N. and lower. With western and northern winds the edge of the ice recedes to the east, the ice becoming somewhat less closely packed; with eastern and southern winds the edge of the ice recedes to the west and the ice becomes much more closely packed. Thus in the eastern part of the Greenland Sea at any time of the year are immense ice-free stretches of water.

THE GREENLAND STREAM

Every year there flows into the Arctic Ocean about 5,000 cubic kilometres of river water. In addition about 30,000 cubic kilometres of Pacific waters and more than 100,000 cubic kilometres of warm Atlantic waters flow into the Arctic basin through the Bering Strait annually. A small proportion of this water passes into the Baffin Sea but the bulk flows into the Greenland Sea through the broad strait between Greenland and Spitsbergen, forming the East Greenland current. This current is maintained and considerably strengthened by the north and north-west winds which predominate on the east coast of Greenland.

As observations have shown, in the central basin, the speed of the constant current towards the Greenland Sea is not great: it is less than one nautical mile a day. But on approaching the Greenland Sea and within the Greenland Sea, the speed of the constant current increases. According to the calculations of Shirshov and Fedorov (of Papanin's North Polar Expedition), near the 83rd parallel the speed of the constant current towards the south reaches 4 km., near the 80th it is 6 km. and near the 75th parallel it is 9 km. a day.

At the end of August 1939, reaching the northernmost point of her drift, the *Sedov* began quickly to descend to the south-west, becoming gradually drawn into the Greenland current. From December 1, 1939, the drift proceeded due south, almost parallel to the drift of Papanin's North Polar Expedition, almost at the same speed with which the latter had drifted in that region two years previously.

During the period of its drift, Papanin's North Polar Expedition descended about 1,120 nautical miles to the south latitudinally. This route was covered under the influence of the constant current and local winds. If account is taken of the data of Shirshov and Fedorov concerning the direction and speed of the current, it appears that about 600 nautical miles of the total length of the drift was due to the accompanying sea currents, and only 520 nautical miles to accompanying winds. At the same time, the theoretical drift for the *Sedov* was shorter than the actual drift by 550 nautical miles, because when plotting it, we gave consideration only to local winds.

Taking into account the observations and calculations of Shirshov and Fedorov, we attempted to calculate the entire drift of Papanin's Expedition caused, on one hand, by the distribution of atmospheric pressure, and on the other, by the constant current. The results of this calculation made by myself with the help of my assistant, Mr. Somov, are of interest. Comparing the actual position of Papanin's North Polar Expedition on February 1, 1938, with the theoretical position, calculated according to my formulæ, with due account of the constant current, we find that the actual position of the Expedition differed from the theoretical position only by 50 miles in latitude, or only by 5 per cent of the total length of the drift in latitude. This comparison may be regarded as bordering on the limits of accuracy with which the original data were obtained.

DEVELOPMENT OF LONG-RANGE AIRCRAFT*

AEROPLANES as a means of transport become increasingly attractive as their range increases. For short journeys the saving in time is often negligible, especially in a country in which other forms of carriage are well developed, but on long routes, particularly trans-oceanic services, the time saved may amount to days or even weeks. Long range demands large fuel capacity, and the peculiar conditions in aircraft may reduce the pay load until it becomes uneconomic, and eventually the limiting range is reached over which no pay load can be carried. The principal problem associated with this is the difficulty of taking a heavily loaded aeroplane off the ground. When flying free, a heavier-than-aircraft is capable of carrying a much bigger load than that which it can lift off the surface of a normal aerodrome. The hazard of a heavily loaded take-off is considerable, particularly when the machine has just left the ground. If at this moment there should be an engine failure (and it is a time when engines appear to be liable to fail, due possibly to some small maladjustment during their overhaul since last being run, which develops into a failure catastrophically) the results will almost certainly be serious, as it is necessary to land at high speed with little or no choice of landing site.

It was with these points in mind that Sir Alan Cobham began several years ago to develop his system of refuelling in flight. His aim was to allow an aircraft to take off light, with very little of the required fuel on board, which on a long-range machine may amount to as much as 25–30 per cent of its all-up loaded weight. Its take-off would thus be comparatively safe, as its preliminary run would be short and the climb away from the ground relatively steep until it has reached a safe operating height. A flying tanker would then come alongside and deliver the fuel to give it range. This scheme has been successful in the regular operation of the North Atlantic service by Imperial Airways Limited last summer, in which the *S*.30 flying boats were refuelled at Foynes or Botwood before they commenced the ocean crossing. These flights are to be resumed during this summer, and will probably continue until the ice on Botwood Harbour closes them down for the winter.

Many methods of assisting the take-off have been suggested, and they may be classified under four headings :

(1) *Improvement of Thrust.* (*a*) Controllable pitch airscrews. (*b*) Ground boosting of the power plant, including the use of high-octane fuel.

---

* Based upon (1) "Report on the Effects of Large Increments in Wing and Power Loadings on the Performance of Aircraft" by Marcus Langley ; (2) "Static Electricity in Relation to Refuelling in Flight" by Marcus Langley and H. M. Barlow ; (3) "Landing Speed and Ceiling in Relation to Refuelling in Flight" by Marcus Langley Flight Refuelling Limited, Ford Aerodrome, Yapton, Arundel, Sussex.)

(*c*) Catapulting, inclined runways, etc. (*d*) Mayo Composite aircraft.

(2) *Reduction of Drag.* Reduction of coefficient of friction by means of bogey on rails, concrete runways, etc.

(3) *Improvement of Lift.* (*a*) Flaps of various designs, including mechanical variation of wing camber. (*b*) Makhonine's span-wise variation of area. (*c*) Use of slipstream and angle of thrust line relative to wing, according to the Crouch-Bolas patents. (*d*) Mayo Composite aircraft.

(4) *Reduction of Weight.* Addition of fuel, subsequent to the take-off, by the methods of Flight Refuelling Ltd.

Combinations of these methods are found in the design of most modern transport and military aircraft. Thus it is now usual to fit an air liner with controllable-pitch airscrews, ground-boosted power plants, and low-drag flaps, to gain some advantage from the slipstream in improved lift, and to operate it from aerodromes having concrete runways. It is only by these methods that loadings as high as those now used are possible, but these are far from being the optimum loadings in flight.

Certain of the methods, particularly those which imply the use of specially prepared aerodromes, are not suitable for military aircraft. Others are not particularly suitable for passenger purposes. For example, the acceleration of a catapult used for a passenger transport would have to be relatively low, and consequently its design would be elaborate, and its cost, weight and dimensions prohibitive. In any event, unless such methods assist the initial climb in order to clear obstructions outside the aerodrome, as well as shorten the take-off run, they provide only a partial solution of the problem. This suggests an alternative classification of these methods:

(*a*) those which are substantially safe; and
(*b*) those which introduce a hazard.

Under the second heading might be put catapults, inclined runways, over-sized aerodromes, and, in fact, any method the assistance of which is withdrawn at the moment the aircraft leaves the ground.

Refuelling is of greatest value in allowing the operation of trans-oceanic air routes of 3,000 miles or more, where no intermediate landing is possible. There is an agreed international limit for take-off run by which a civil aircraft must be able to clear a 60 ft. barrier 656 yards from its starting point. It is possible to design a normal modern air liner capable of carrying a reasonable pay load over a distance of 3,000 miles, and to keep within this limit of take-off. Additional range, demanding extra weight of fuel, can only be had at the expense of lengthening the take-off run and reducing the angle of climb, or alternatively reducing the pay load. If the machine were refuelled after leaving the ground, its take-off could be reduced by half.

A similar air liner could be designed which, with the aid of refuelling, would be able to fly 5,000 miles with about the same pay load as that carried by the normal machine for 3,000 miles, and its take-off run would still be less than 400 yards with an angle of climb of $11\frac{1}{2}°$. The corresponding normal aircraft would require more than 1,000 yards if it had to take this load off the ground, and it could climb at an angle of only 5°.

Many practical problems have had to be solved before the process could be considered sufficiently safe and reliable for everyday use. A complete set of equipment has been developed for both the tanker aircraft and the machine which receives the fuel. Flying problems have had to be explored, so that the operation could be carried out in any condition of weather in daylight or at night.

It is now simple and quick. The receiving aircraft flies a straight and level course when it has climbed to its operating height. It streams out a hauling line with a sinker weight attached through the receiver coupling in its tail, and the tanker comes up behind and to one side, and fires a line across this. The contact thus having been established, it is a simple matter to attach the nozzle of the hose pipe to the receiving aircraft's hauling line. The hose is paid out and the nozzle pulled by a windlass into the coupling, where it is retained by hydraulically operated claws. During this coupling-up process the tanker has climbed into the refuelling position above, behind and to one side of the liner. Approximately 200 ft. of hose is used for a separation between the aircraft of 100 ft. The hose thus trails back in a hairpin bend, and if it were to break or come adrift it would fall clear of both machines. The coupling is non-jammable and is fitted with an automatic release, so that the nozzle will come away should it be necessary for the aircraft to part in an emergency. For the Atlantic service, a 2-in. bore hose was used, and with a gravity head of 60 ft. the rate of flow was of the order of 110 gallons a minute. The whole process of transferring 800 gallons took 12–15 minutes, of which about five minutes was spent in making contact and getting the hose across, and some seven minutes in actually passing the fuel.

Among the many interesting secondary problems were those associated with static electricity. The two aircraft might be at a different potential and charges might be built up in the hose pipe due to friction. There was a further chance of electrification by splash as the petrol rushed into the receiving tanks. Methods have been evolved to overcome all these possible dangers. The two machines are completely bonded together throughout the whole process by means of the spiral steel wire armouring on the outside of the hose pipe. The whole system is flushed through with nitrogen from the tanker both before and after the passing of the petrol. At the moment of break-away, the contents of a bottle of methyl bromide are automatically sprayed into the receiver coupling, and the final contact is eventually broken in mid-air by snapping a weak link in the hauling line as the aircraft part company.

It is difficult to foresee all of the ramifications of the post-War developments of civil aviation, but the establishing of rapid transport of mails and passengers over the long ocean routes between the continents is one of the most obvious. This will scarcely be possible as a self-supporting economic proposition with present-day aircraft, unless in the meantime some revolutionary discoveries are made either in the aerodynamic design of aircraft, or in the design of power units. It is possible to visualize at least an approach to this ideal by making use of refuelling in flight, using the most up-to-date design of aircraft as now accepted. During the War its development is going on, but little may be said about its possibilities for military purposes.

OBITUARIES

Dr. R. T. Gunther

WE regret to record the death on March 9 of Dr. Robert William Theodore Gunther, a great student of science and the founder in the Old Ashmolean Building of the Oxford Museum for the History of Science. With him there passes the last of the Oxford science tutors appointed in the early and middle 'nineties and a learned, aloof, enigmatic, single-minded and essentially good man.

Gunther was born in 1869, the eldest son of Dr. Albert Günther, the zoologist, and educated at University College School, London, and Magdalen College, Oxford. He had wide scientific interests as a boy—in geography, chemistry, practical mechanics and biology. The combined influences of his father and of Ray Lankester, whom Gunther greatly admired, led him to take his B.A. degree in biology. He obtained, as one could in those days, a first class in morphology in 1892, and shortly afterwards was appointed tutor in science at Magdalen. A few years later he became a fellow. Few men read science at Magdalen in the 'nineties, and Gunther, unlike the busy tutor of to-day who divides his time between work and research in the laboratory and tutorial hours in college, was a free man. He went with an endowment to Naples to work in the Marine Laboratory there, and between 1897 and 1914 travelled widely, studying the natural history of lakes in Persia and the geology of extinct volcanoes and surveying the entire coast-line of Italy. His first publications were on subjects in biology and geology, but his intense devotion to the memory of Prof. Charles Daubeny of Magdalen College helped to deflect his interests from the present to the past, from Nature to documents and instruments, from research in laboratories to pieces in museums. His history of the Daubeny Laboratory of Magdalen College came out in 1904, and annotated registers of those who had worked in it were published in 1916 and 1924. His love of collecting material relating to the past and arranging it for publication was shown in his monographs on his own family, on his wife's family, on the monuments in Magdalen Chapel, and similar subjects, brought out in the period 1910–14.

After the War of 1914–18, Gunther devoted himself to collecting for exhibition scientific and mathematical instruments of the past, especially of Oxford's past, and to editing the little-known or forgotten works of Oxford's early scientific men, of whom Robert Hooke was first favourite. In the period 1920–37 he brought out no fewer than eleven volumes on these men and their works, in addition to works on astrolabes, early libraries, and other subjects. Anything 'early' and 'scientific', even in Cambridge, whatever its present relevance or value, interested him greatly and, he believed, would interest others too. One old instrument, blunt and rusty, one old book, with a few good scientific ideas in it, gave him joy when ninety-nine particle-counters or up-to-date text-books left him lukewarm. It was unfortunate that some of the publications received adverse and even trenchant criticism. It was not that Gunther was constitutionally inaccurate or that he would not take sufficient trouble with his material; it was that he would do everything himself. He never collaborated or took advice. He went his own way. He did his best. When up against a difficulty he preferred to surmise rather than to seek someone who knew the answer. This temperamental weakness was best revealed in his large work on early astrolabes where criticism which he could have got in Oxford, indeed, in his own College, was delivered more vigorously than helpfully after, instead of before publication.

During the War of 1914–18 Gunther became curator of the Botanic Garden in Oxford, and from 1920 until 1923 the librarian of Magdalen. In the 'twenties the rooms in Daubeny's buildings, where he was amassing his instruments and books, with Daubeny's eighteenth century chemical-ware as its nucleus, were needed as lecture rooms and laboratories. Gunther took it ill when his College asked him to leave and take the material elsewhere. There was, in consequence, a breach, inevitable between a College alive to the needs of the twentieth century and one who was essentially a seventeenth century antiquarian. The breach, however, brought out the best in Gunther's fighting qualities. He determined that Oxford should have a museum for the history of science that would be unique. Almost no one in Oxford but himself was interested in that kind of museum. He set out, decisively and even gallantly, to achieve his purpose. He had a talent for relating means to ends, for making just so much impression on individuals and colleges as would extract from them what he wanted, for doing just so much canvassing as was needed to gain his particular point in the courts of the University. At times he did not invite, he commanded; city magnates came to Oxford to unveil memorial windows; presidents of the Royal Society came at his bidding to commemorative luncheons; chancellors and heads of colleges signed his appeals in *The Times*. In 1924 he became the curator of the Lewis Evans collection of scientific instruments, and this nucleus became the museum for the history of science in the Old Ashmolean building in Broad Street, Oxford, in 1935. To-day the collection is unique and, but for the War, would be in a lovely setting. Gunther's single-handed fight to collect this material and to get it into the building, where it now is, will not have been in vain if someone can now be found to succeed him as curator and in the University readership in the history of science. The museum is his fine achievement, a witness to what one man by himself can do.

Gunther married Amy Neville-Rolfe, daughter of a former consul-general at Naples. He had two sons, the elder of whom was zoologist to the recent *Discovery* expeditions. A. S. RUSSELL.

Prof. D. S. Margoliouth, F.B.A.

WE regret to record the death of Prof. D. S. Margoliouth, for many years a foremost authority in Oriental studies and formerly Laudian professor of Arabic in the University of Oxford, which took place on March 22 in the Middlesex Hospital, London, at the age of eighty-one.

David Samuel Margoliouth was born in 1858 of Hebrew Polish stock. The son of an Anglican missionary to the Jews, he was educated at Winchester and New College, Oxford. Both at school and at the university he was of outstanding ability, and showed a remarkable and unusually early maturity in classical studies, being awarded both the Hertford and the Ireland Scholarships in his first year as an undergraduate. Later he turned to Oriental studies, winning all the University prizes open to him in this field. In 1881 he was appointed fellow and lecturer in classics; and eight years later he entered upon his occupancy of the Laudian professorship, which he held until his retirement only three years ago.

Margoliouth's knowledge of the Arabic language and literature was universally recognized as unrivalled in either Europe or the East. His unremitting activity in this branch of Oriental studies was devoted to the editing and elucidation of the more difficult and obscure of classical Arabic texts. Here his greatest achievement was his monumental edition of Yakut's "Dictionary of Learned Men". Next to this must be ranked his work in collaboration with H. F. Amedroz on the Abbasid chronicles of Miskawaihi. Commentators on Aristotle and the Old Testament also engaged his attention—he produced an edition of the Poetics—and he collaborated with Dean Payne Smith in the "Thesaurus Syriacus".

Those who are acquainted with Margoliouth only through his more highly specialized literary and linguistic studies may possibly fail to realize how deep and wide were his interest in and knowledge of the content of the texts he studied and, in short, of the whole range of the thought, culture and beliefs of the peoples of the Arabic tongue. His profound knowledge of the early development of Islamic belief is to be observed in some degree in his Hibbert Lectures delivered in 1913 and in the two books which appeal to a wider audience, "Mohammed and the Rise of Islam" and "Mahammedanism", the latter a volume in the Home University Library. His erudition was ever freely at the service of those whose studies lay in any cultural sphere impinging in any way upon his own, and appeal for enlightenment was never made in vain.

The Polish Government Information Department has issued a communiqué stating that up till February 1 the following professors, among others, of Polish universities have died in the concentration camp Sachsenhausen-Oranienburg, or have died since their release from camp:

Tadeusz Grabowski (philosophy);
Antoni Hoborski (mathematics);
Kazimierz Kostanecki (comparative anatomy);
Jan Nowak (geology);
Feliks Rogoziński (physiology);
Adam Różański (agricultural mechanics);
Michał Siedlecki (biology) [see NATURE, March 30, p. 492];
Jerzy Smoleński (geography);
Władysław Takliński (technology);
Antoni Wilk (astronomy);
Jan Włodek (agriculture).

We regret to announce the following deaths:

Prof. J. W. Beede, formerly professor of geology in Indiana University, an authority on the geology of Texas, on February 27, aged sixty-eight years.

Prof. Alexandre Besredka, chief of the section of microbiology of the Paris Pasteur Institute, aged seventy years.

Prof. S. M. Dixon, O.B.E., formerly professor of civil engineering in and dean of the City and Guilds College, London, on March 25, aged seventy-two years.

Mr. J. A. Hobson, the well-known economist, on April 1, aged eighty-one years.

Prof. A. E. Norton, since 1935 Gordon McKay professor of applied mechanics in Harvard University, on February 24, aged sixty-two years.

NEWS AND VIEWS

CHAIR OF CRYPTOGAMIC BOTANY AT MANCHESTER

Prof. W. H. Lang, F.R.S.

THE Barker chair of cryptogamic botany in the University of Manchester will be vacated at the end of the academic year by its present tenant, Prof. W. H. Lang. His successor has been appointed in the person of Dr. Claud Wardlaw, officer in charge of the Low Temperature Research Station at Trinidad. He is expected to take up his duties in the autumn. The founder of the Barker chair was himself an expert in the study of mosses: and his aim was to secure not merely instruction, but also general research upon those lower forms of plant life which the title of the chair connotes. In order to secure this double result, such periods of advanced teaching as are demanded from the professor are limited, thus leaving opportunity for research to him and to his pupils.

Since such conditions are exceptional, the appointment to the Barker chair commands a special interest. The distinction of its out-going occupant is well known, and was recognized by the award of a Royal Medal in 1931. Prof. Lang, having qualified in medicine in the University of Glasgow, drifted into the specialized pursuit of botanical science after having graduated with distinction also in science in 1894. In the years that followed he carried out various researches, chiefly upon archegoniate plants and gymnosperms. These marked him out as an acute experimentalist and observer, so that when the Barker chair was founded in 1909 the appointment seemed naturally to fall to him. From the first his use of observed fact was strictly critical, and his approach to constructive conclusions very guarded. These qualities are such as are specially required in palæophytology, towards which circumstances seemed to have been conspiring to guide him. For while still officially in Glasgow he had become acquainted with that prince of palæontologists, Robert Kidston, of Stirling: and was not Manchester the place where Williamson had enshrined his own peculiarly exact study of fossil plants?

After Lang's appointment to the Barker chair, the results of a happy co-operation with Kidston culminated in the five memoirs "On Old Red Sandstone Plants showing Structure, from the Rhynie Chert Bed, Aberdeenshire". Published in the *Transactions of the Royal Society of Edinburgh* (1916–1921), this series, together with that of Kidston and Gwynne-Vaughan on "The Fossil Osmundaceæ", will stand for all time as twin models of method in palæophytological research. Moreover, each deals with results of supreme importance to the comparative morphology of vascular plants. The Rhynie memoirs are perhaps the most striking record of Prof. Lang's researches. But since their completion, his laboratory has been a centre of elaboration of palæontological method, and of its application to other fossils, particularly those of very early time. He has thus laboriously gathered data which, though largely dealing with isolated facts, will ultimately take their place in the jig-saw puzzle, still very imperfectly sketched, of the earliest flora of the land.

Dr. C. W. Wardlaw

DR. C. W. WARDLAW, officer-in-charge of the Low Temperature Research Station, Imperial College of Tropical Agriculture, Trinidad, has been appointed to succeed Prof. Lang. Dr. Wardlaw graduated in 1921 with first-class honours in botany in the University of Glasgow and was immediately appointed assistant to the professor of botany, Prof. F. O. Bower. He carried on the Bower tradition with research on size and form in stellar structure and developed research and teaching in mycology at Glasgow. Three years later he took the Ph.D. of Glasgow and was appointed lecturer. He was sent to study mycology under Brown at the Imperial College of Science and Technology, London, and also visited Prof. Chodat's summer school in Switzerland. He took his D.Sc. degree with papers on size and form and studies on the Lanarkshire strawberry disease. He was often called in as consultant on various diseases in Scotland. In 1929 Dr. Wardlaw was appointed mycologist at the Imperial College of Tropical Agriculture, Trinidad, and undertook investigations into diseases of the banana. Later he took charge of the investigations of cold storage in particular reference to the mycological aspects, and has travelled a great deal in the West Indies and in the north of South America.

It may be thought that to appoint an expert on banana investigations as successor to so distinguished a palæontologist as Prof. Lang would be a dangerous experiment, but Dr. Wardlaw is in point of fact an all-round botanist, with a bias towards the Cryptogams. His first work was on a parasitical disease of cultivated strawberries. Then followed three searching memoirs on "Size and Internal Morphology", with illustrations, mainly cryptogamic, drawn to uniform scale. Later came a series of memoirs on the fungal diseases of the banana; and again, another series based on experiments at the Low Temperature Research Station at Trinidad. These deal with that phase of physiology which is involved in the successful transport of tropical fruits to serve the home markets. Such results, together with descriptive records of wide travel among the West Indian Islands and on the mainland of Central America, reveal Dr. Wardlaw as a botanist of broad interests, who has used his exceptional opportunities for observation and reasoning to good purpose. A botanist so versatile in what he has already accomplished may be trusted to continue the tenure of the Barker chair along lines in accord with the will of its founder.

Royal Irish Academy: New Professor of Theoretical Physics

AT the election meeting of the Royal Irish Academy in Dublin on March 16, it was announced that Dr. Erwin Schrödinger had been appointed professor of theoretical physics in the Academy as from April 1. The funds for the professorship are being supplied to the Academy by the Irish Government. Prof. Schrödinger has been giving a course of lectures on wave mechanics at University College, Dublin, since November last. This course has had a large attendance from members of the two Dublin Colleges. It will be continued now in the Royal Irish Academy.

It is believed that the institution of this professorship is intended as a temporary measure, pending the setting up of an institute for theoretical physics in Dublin, in which Prof. Schrödinger will have a permanent appointment. The recent publication of the text of a Bill making provision for the new institute shows that Mr. de Valera does not intend the financial difficulties arising out of the War situation to upset his plans for the development of higher mathematical studies. In addition to mathematics and theoretical physics, the mention of cosmology, geophysics and even chemistry in the Bill may be taken as indicating that Mr. de Valera has in mind the possibility of the institute broadening the scope of its studies in the future. There is also to be an institute for the promotion of higher Celtic studies.

Prof. H. Arctowski

WITH home, laboratory, and invaluable records of years presumably irrevocably lost during the War, Prof. Henryke Arctowski, formerly honorary professor of geophysics and meteorology in the University of Lwow, has begun work at the Smithsonian Institution on the direct effects of changes in the sun's radiation on weather conditions on the earth. Prof. Arctowski is recognized as one of the greatest authorities on world weather. He has now started with renewed enthusiasm on the correlation of solar and terrestrial phenomena from the comprehensive records of the Smithsonian Astrophysical Observatory. He has already made significant—although for the present tentative—findings of apparent cause-and-effect relationships between the variation of solar radiation and terrestrial weather conditions.

John Dixon Mann

DR. JOHN DIXON MANN, an eminent Manchester toxicologist, was born in 1840 at Kendal, where his father was borough treasurer. He received his medical education at the Manchester Royal School of Medicine and qualified M.R.C.S. and L.S.A. in 1862. For many subsequent years he was engaged in general practice in Manchester, but in 1880 he became M.R.C.P.(Lond.) as well as M.D. of St. Andrews, and confined himself to consultant practice. In 1882 he was appointed physician to the Salford Royal Hospital, and three years later became lecturer in forensic medicine and toxicology at Owens College, Manchester, in succession to Dr. C. J. Cullingworth, who was elected professor of obstetrics and gynæcology. The lectureship was converted into a chair in 1892. Dixon Mann's principal work, "Forensic Medicine and Toxicology", which won him the Swiney Prize awarded by the Royal College of Physicians of London and the Society of Arts, went through four editions between 1893 and 1907 and was for many years the standard work on the subject. His other book, entitled "On the Physiology and Pathology of the Urine with Methods for its Examination", appeared in 1904 and was followed by a second edition in 1908. He also made numerous contributions to periodical medical literature including the *Medical Chronicle*, the now extinct Manchester journal, which contains a bibliography of his writings. He died on April 6, 1912.

Hindu and Moslem in India

THE course of recent events in India tends to confirm apprehension, such as has found expression in the columns of NATURE from time to time while the terms of the new constitution were under consideration, lest the introduction of the forms of Western democracy among a population of so heterogeneous a character in culture, creed and tradition might encounter difficulties well-nigh insuperable. It was hoped by those responsible for decision that the communal solution would at once secure the rights of minorities and ensure their acquiescence in the rule of the majority which is essential for the successful working of democratic institutions. It has been made evident by subsequent events that the necessary community of outlook was lacking. This is to be seen on one side in the breakdown under provincial autonomy, on the other in the difficulty in formulating a scheme of federation in which the claims of democracy can be reconciled with the autocracy of the native States and the fears of the Princes lest they should endanger rights based upon tradition and further secured by the treaty with the British Crown.

A situation which bristles with difficulties and requires the most delicate handling has been brought within measurable distance of a crisis in the turmoil of world events. The Indian Congress, the representative body of the Hindu community, has seized the opportunity to put forward a claim for the grant of that independent status for India towards which it was hoped the new constitution would serve both as a stage and a training ground. This claim the Moslem League has countered by a demand for the recognition of separate Moslem and Hindu nations within the bounds of India. The demand is by no means so fantastic as it may appear at first. Apart from the fact that the voice of a minority of some eighty millions or more, sectional differences for once forgotten, cannot be ignored, it is based upon a very real difference in a cultural tradition, as every student of Indian civilization is aware; for the Moslem tradition fosters a democratic outlook while fearing and resenting a Hindu domination in an independent India, which would from its immemorial tradition of caste be essentially oligarchic in practice. However impracticable the Moslem demand may be, no solution will secure the future of India in world affairs or internally which attempts to ignore or override these fundamental differences of culture and tradition.

New Government Technical School at Takoradi

The opening of the new Government Technical School at Takoradi introduces a further development of this type of education in the Gold Coast. Increased demand for technical instruction necessitated the removal of the school from Accra, where the accommodation proved to be inadequate. Moreover, the new site is more favourably placed in relation to the industrialized area of the Gold Coast. The new Technical School occupies a prominent site overlooking the sea and Takoradi Harbour, and the more important buildings include a long single-story workshop with blacksmith's shop at the rear, a three-story administration block containing classrooms, laboratories, drawing offices, assembly hall and dining-room and a dormitory block capable of housing one hundred students. The workshop is in two sections, one for practical work in mechanical engineering and the other for practical woodworking. Both sections are fitted with modern electrically driven machinery such as lathes, power drills, shapers, etc., in addition to the usual benches for manual work.

Other buildings include the European housemaster's bungalow, two blocks of quarters for eight African masters, a block of six labourers' quarters, a large timber-drying store, petrol store and garage. The buildings are grouped around a five-acre sports ground. In addition, there are facilities for safe sea-bathing and boating. The buildings are fitted with electric clocks controlled by a master clock; most of the classrooms and the assembly hall are wired for the reception of wireless re-diffusion from the Sekondi broadcasting station; and there is complete water-borne sanitation. Candidates for admission must be in possession of a Standard VII Certificate or its equivalent. Present students include boys from Nigeria, Dahomey and all parts of the Gold Coast. Among entries for next year are three boys from Sierra Leone. The total cost of the scheme has been approximately £37,500, which includes approach roads, laying out of grounds, etc., the area covered by the school and grounds being some thirty acres.

Fishery Research in the Italian Empire

The rapidity of scientific development in the new Italian Empire is well illustrated by the subject of aquatic biology. Only three years have elapsed since the conquest was complete, and yet the recently formed Direzione Superiore Affari Colonizzazione e Lavoro has already set up an Ufficio Idrobiologia e Pesca at Addis Ababa, under the direction of Prof. P. Parenzan, and a considerable amount of preliminary research has taken place on the inland waters of the former Ethiopia. These are described in the first number of a new official journal entitled *Bollettino di Idrobiologia, Caccia e Pesca*. It is a well-appointed publication, containing papers on fish, their importance in the food of native peoples, parasites and pathology, and accounts of other aspects of the biology of fresh waters, including the fish-eating birds and Mollusca.

Meanwhile, in the past half century, the vastly greater areas of lakes and rivers in British eastern Africa, containing correspondingly greater resources, have been subjected only to spasmodic and short-term scientific examinations, and most of these have resulted from the initiative of individual scientific workers or institutions not immediately concerned with colonial development. Perhaps the new policy in colonial research and development which has recently been announced by the Colonial Secretary may lead, after the War, to the inclusion of fisheries in both the sea and fresh waters in a widely planned scheme of research.

Paratypical Forms in Man's Line of Descent

In a discussion, and incidentally a criticism on certain points, of the announcement of the discovery in Java of an upper jaw attributed to *Pithecanthropus erectas* (see Nature, **144**, 926; 1939), Prof. G. Montandon brings forward a suggestion which he argues would resolve certain of the difficulties inherent in apparent discrepancies in the evidence (*Rev. Scientifique*, **78**, 1; 1940), and maintains that had Dr. von Koenigswald included the palatal view of the jaw in the figures accompanying the announcement of the find, it would have been evident that Pithecanthropus stands outside the Hominidae. Prof. Montandon says that its shape is that of the U characteristic of the anthropoid jaw and not that of the horseshoe form found in man. Further, the simian diastema separating the incisors and canines is present here, though never found in man. At the same time, this disparity does not warrant classification of the jaw as that of a gibbon or other form of anthropoid. For, as Prof. Montandon goes on to point out, the teeth and especially the canines are not Simian but those of a Hominid. Comparison of the jaw with that of Sinanthropus definitely places the latter as belonging to a more advanced type and within the Hominid group.

The discussion becomes even more suggestive when Prof. Montandon passes on to consider the significance of Dr. Broom's recent discoveries in South Africa. Here in Paranthropus is a form which shows a like combination of incompatible characters. In cranial form Paranthropus is more Simian than Hominid, but at the same time in form of jaw and teeth it is the reverse. The jaw shows the horseshoe form, the absence of diastema, and a humanoid dentition. Prof. Montandon therefore goes on to ask the question, pertinent on his interpretation of the evidence, whether there may not be another form in which, as with Pithecanthropus, the cranium approaches the human more nearly than do the Paranthropoids of South Africa, but less human than them in respect of the dental arch. His further suggestion of a whole series of paratypes of wide distribution raises an interesting and wide question which at present rather hangs in the air.

Evolution Restated

THE mathematicians and physicists refer things no longer to three axes of co-ordinates, but to four, the fourth being the time axis. The world is 'four-dimensional', and is a world of *events*. This conception of time as intrinsic to things and not just something that happens to them, is applicable to the biological no less than to the physical sphere, and leads to interesting results, especially as bearing upon the theory of evolution. Some of these corollaries have been indicated by Mr. J. C. McKerrow in a pamphlet "Evolution without Natural Selection" (London: Longmans, Green and Co., Ltd.) supplementing his "Novius Organum" (1931). The Darwinian theory was that out of a number of chance or random variations a certain number were chosen by 'natural selection' to survive. The difficulty for the Darwinian has always been to account, not for 'natural selection' or survival, but for the occurrence of the variations themselves. But it is obvious that if an organism is a 'four-dimensional process' or a system of activity, an event and not a thing, it is not so much variations as repetition and sameness that call for explanation. In a world of events, things happen, whereas in a world of static fixtures, they do not.

Mr. McKerrow, like Samuel Butler, interprets organic activity (and an organism which as a four-dimensional process *is* itself an event, that is, activity, not a thing) in terms of habit. Habit accounts for sameness or stability, but it also accounts for variation, because it does not exclude freedom. "All the forces of nature that make for change are just as much available on the assumption of 'habit' as on that of mechanistic causation—with an additional element of 'fortuity' added". On this view, variations are not so much random as "manifestations of the peculiar degree of freedom of living systems". Evolution on this view is positively, not negatively, conditioned. Hypothetical variations are not produced in order to be massacred by natural selection. It is just a case of a four-dimensional Nature displaying its activity in new happenings. In any event a four-dimensional biology can scarcely leave unchanged our views of the mode of evolution.

Antimony Treatment of Kala-azar

AN article under this title by Sir Leonard Rogers appeared in NATURE of December 16, 1939, p. 1103, which presented in very bare outline the history of the use in India of antimony compounds to combat kala-azar. Sir Upendranath Brahmachari, whose work in connexion with the introduction and use of urea stibamine was referred to briefly, has submitted to NATURE a long statement surveying in some detail the work which led up to the preparation of this substance and reporting on the results obtained. He states that, contrary to Sir Leonard Rogers' statement, urea stibamine was not patented, and claims that divergent results obtained by different investigators were due to the fact that various manufacturers put on the market so-called urea stibamine which did not conform to his specification. Reference is also made to the cost of treatment with antimony compounds. Sir Leonard Rogers stated in his article that a course of treatment with urea stibamine cost £3 in 1925. In the intervening years, this has happily been reduced; Sir Upendranath states that urea stibamine is now supplied by the Government at Rs. 1 per gram, and since 1·5 gm. is sufficient for complete cure, the total cost of the drug to-day is now Rs. 1.8 (about 2*s*. 3*d*.). This is a reduction on which all who have been concerned are to be congratulated. Yet this cost is still relatively high for a country in which the great majority of the population live dangerously near the starvation line, and there is still room for a rapidly effective and really cheap remedy for kala-azar.

American Archæology and Local Research

IN view of recent references in NATURE to the stimulation of local interest in archæological research in the United States of America through Federal, National and State funds, it may be of interest to note that the Research Committee of the American Philosophical Society, in awarding grants in the natural and exact sciences from the Penrose Fund in 1938–39, allocated amounts as follows for localized anthropological and archæological investigations. These are additional to continuing grants for researches to which reference is made in another column of this issue of NATURE (see p. 558). To Emil W. Hanry, of the University of Arizona, for the excavation of a prehistoric village on Forestdale Creek, Fort Apache Indian Reservation, Arizona, an area of direct contact between the Mogollon and Anasazi cultures, 500 dollars; Margaret Lantis, University of California, for an ethnographical study of the complete seasonal round of the year of Alaskan Eskimo, 950 dollars; and Louis W. Chappell, West Virginia University, for the collection and preservation of folk-lore in West Virginia, 500 dollars. The last-named research should prove of special interest in view of its bearing upon cultural exchange between the three strains of white, Indian and Negro. The Indian in the past has suffered in both directions of over-idealization and undue depreciation arising from culture clash. The scientific study of Indian cultures by ethnographical and archæological methods is rapidly widening appreciation in truer perspective.

History of Artificial Eyes

THE January issue of the *Annals of Medical History* contains an interesting account, accompanied by numerous illustrations, of the ancient origins of artificial eyes by Dr. Gordon M. Bruce, of New York. The earliest artificial eyes about which there is definite information were made in Egypt for the adornment of mummies, mummy masks and statues, of which many varieties are to be seen in museums. Artificial eyes have also been found in Aztec and Inca mummies, as well as in mummified specimens from Darnley Island in the Torres Strait and the Solomon Islands. The ancient Syrians were familiar with the use of artificial eyes, as is shown by a specimen in the Metropolitan Museum of New York. The existence of artificial eyes in Babylonian times has recently been proved by the discovery of a cuneiform inscription of about 1600 B.C., in which 22 artificial eyes, 9 of agate and 13 of chalcedony, are mentioned. In ancient Greece statues were often provided with artificial eyes, Pheidias's statue of Athena being a celebrated example. In ancient Rome the *faber ocularius*, or maker of artificial eyes, existed as well as the *medicus ocularius*, who was a favourite subject for contemporary satirists, especially Martial. There is no definite description of artificial eyes to replace those lost by disease or accident before the middle of the sixteenth century, when they are mentioned by Ambroise Paré, but, as Dr. Bruce points out, the terms in which he speaks of them do not indicate that they were an innovation at that time.

The Development Commission

THE twenty-ninth report of the Development Commissioners, for the year ending March 31, 1939, has just been published (H.M. Stationery Office. 2*s*.). The total sum recommended for the fund was £625,642, of which agriculture and rural industries accounted for £579,480, and fisheries and harbours £46,162. These grants, particularly in the latter case, were rather smaller than in the previous year, when the amounts were £608,911 and £131,555 respectively. A short section describes the subject of study, size of staff and total sums available for expenditure at each of the agricultural research institutes in receipt of grants from the Fund, but details of their work are supplied in other publications. Results accruing from grants are necessarily difficult to assess, but it must be remembered that it is largely through her research institutes that Great Britain maintains such a close touch with agricultural science throughout the world, and has been able to assist in Empire development through supplying trained men.

As regards rural industries, the greater part of the sum allocated has taken the form of grants to the Rural Industries Bureau. The latter exists both to help the craftsmen for their own sakes and to maintain the village workshop for the sake of the country. By its advisory service and the introduction of improved equipment and methods of business it is hoped to secure the interest of the younger generation in industries of vital importance to the farmer. Investigations undertaken by the Fishery Departments are largely carried out under schemes adopted by the International Council for the Exploration of the Sea. Both the English and Scottish share of the investigations receive support from the Fund, and grants have also been made for research on freshwater fisheries.

Colorimetry of Electric Discharge Lamps

IT is claimed in the *G.E.C. Journal* of February that during last year very satisfactory progress was made in developing various types of technique for improving electric discharge lamps. Unsolved problems in heterochromatic photometry and colorimetry previously stood in the way. The problem was complicated by the practical application of fluorescent discharge lamps to domestic and other forms of interior lighting. This made it necessary to measure the colour-rendering properties of the light sources in a way distinct from their colour. Although non-selectively reflecting surfaces or fabrics, such as 'whites' or 'greys', will have the same coloured appearances when illuminated by light from such sources, since reflection by these surfaces produces no change in the spectral energy distribution of the light, the coloured appearance of selectively reflecting surfaces, such as dyed fabrics, may be quite different. Therefore, although the colour of these two light sources is the same, their colour-rendering properties are different, and it is this latter property which it is desired to measure.

Two types of measurement are made: (*a*) the determination of the most desirable colour-rendering properties of light sources when performing different tasks at different illuminations (this involves major research into chromaticity scales under different observational conditions); (*b*) the recording of the spectral luminosity distribution of light sources already established as satisfactory for particular purposes, so that the manufacture of such lamps can be controlled in a manner to ensure uniformity of colour-rendering properties of the commercial lamps or fittings. These measurements are carried out by visual photometric measurements of spectral luminosity made, in turn, through a series of spectral filters which transmit light only within defined wavelength limits. This involves a comparatively simple technique which can be undertaken commercially with photometric apparatus. For differentiating and defining the colour-rendering properties of many electric discharge lamps, this method is not sufficiently sensitive. One recent method, which is being used to define the luminosity distribution throughout the spectrum, utilizes physical photometric methods of measuring the relative luminosity in eight suitably chosen adjacent spectral bands, extending throughout the physical spectrum.

Trench Fever

IN his inaugural thesis (*Thèse de Paris*, No. 870; 1939), Dr. Robert Schapiro remarks that since the War of 1914–18, during which trench fever was very prevalent both on the French and Italian fronts as well as in Salonica and Mesopotamia, endemic cases have been reported in the south of France and Russia. It is also probable that many cases have passed unrecognized. Reports received from Spanish doctors living in their own country or as refugees in France indicate that there has been an outbreak of the disease in Spain, although Schapiro has been unable to obtain confirmation of this from other sources. The possibility, however, of a return of the disease must be recognized in view of the fact that defective hygienic conditions, and particularly the presence of lice among the troops, favour the spread of trench fever.

Moreover, the risk of its occurrence is increased by the transfer last autumn of German troops from east to west, as the disease is undoubtedly more prevalent in Central Europe than in the west. Soldiers, however, are not the only persons liable to contract the disease, although they were chiefly affected during the Great War, but owing to the contacts between the army and the civil population the latter are also liable to become infected, especially in the case of large agglomerations and refugees. Although trench fever is not a serious disease in itself, it may be the cause of a considerable degree of invalidism, as is shown by the fact that Sir Wilmot Herringham calculated at eight million the total number of days off duty in the British Army due to this cause. Prevention consists in immediate isolation of the first cases, delousing of contacts and other methods for the destruction of lice.

Miniature Circuit-Breakers

THE *Electrical Review* of March 29 points out that an amendment has been made by the Standards Association of Australia to its wiring rules, by a provision that the loading of final sub-circuits may be increased if sealed circuit-breakers of an approved type are used in place of fuses. In this case two general purpose socket outlets in a room of a dwelling-house can be counted as one if connected with an 8, 12 or 18 ampere final sub-circuit, and any permanently connected appliance rated at 100 watts or less may be counted as a lighting point. It is stated that in many cases the additional cost of the circuit-breaker will be largely offset by the reduction in the number of fuses required. While the Wiring Rules of the Standards Association of Australia differ materially from the Regulations of the Institution of Electrical Engineers, thus precluding the possibility of direct comparison, the value of a circuit-breaker the setting of which cannot be tampered with would in many cases be high.

The Science Masters' Association

THE report for 1939 of the Science Masters' Association records a rapid growth in membership. Last year no fewer than 914 schools were represented, whereas twenty years ago there were only 143. So extensive a combination can produce effective action, which we notice in the first annual report of the London and Home Counties Branch. Suggestions on the new physics syllabus of the London General School Examination were made after discussion, sent to the general committee of the Association, passed on, and accepted. The result is changes which are announced to "take effect in the physics paper at the next examination".

Memorandum on Scabies

SCABIES, or the 'itch', is a superficial inflammation of the skin caused by infestation with the itch mite, the female of which burrows into the skin producing much irritation. The affection is very liable to occur among collections of persons living together in restricted circumstances such as are met with in war-time, among evacuee children, soldiers and others. The Ministry of Health has therefore issued a useful memorandum on the subject (Memo. 229/Med. H.M. Stationery Office. 2*d*. net). It describes the affection and its complications, diagnosis, methods of spread and prevention, and the treatment.

The Iron and Steel Institute

MR. JOHN CRAIG, chairman and managing director of Messrs. Colvilles, Ltd., has been elected president of the Iron and Steel Institute for the next two years. Mr. Craig will be inducted into the presidential chair by the retiring president, Lord Dudley, at the annual general meeting on May 2. The Bessemer Gold Medal for 1940 of the Institute has been awarded to Dr. Andrew McCance, of Glasgow, in recognition of his eminent services in connexion with the application of science to the iron and steel industry. Dr. McCance is a director and general manager of Messrs. Colvilles, Ltd. M. Eugène Schneider has been nominated an honorary member to celebrate the fiftieth anniversary of his election to membership. M. Schneider joined the Institute in 1890 and was president for the period 1918–20. An Andrew Carnegie Silver Medal has been awarded to Mr. Bo W. L. Ljunggren for his memoir entitled "Method of Sclero-grating employed for the Study of Grain Boundaries and of Nitrided Cases; Grain Structures revealed by Cutting". The Williams Prize for 1939 has been divided between Mr. W. B. Lawrie, for his paper on "The Refining of Metal in the Basic Open-Hearth Furnace. The Influence of Fluorspar on the Process", and Mr. W. T. Wilson, for his paper on "The Rolling of Sections at the Appleby-Frodingham Steel Company, Limited." No papers have been received in competition for the Ablett Prize for a paper on a subject connected with engineering in iron and steel works written by a junior engineer. Captain Ablett has renewed the offer of the Prize for competition in 1941. Particulars can be obtained from the Secretary of the Institute; papers must be submitted not later than January 31, 1941.

Announcements

THE annual joint meeting of the Institute of Radio Engineers and the American Section of the International Scientific Radio Union will be held at the National Academy of Sciences, Washington, D.C., on April 26. A programme of abstracts will be available in booklet form about April 15. Correspondence should be addressed to S. S. Kirby, National Bureau of Standards, Washington, D.C.

A RESEARCH department for racial hygiene has recently been created in the Welfare Ministry in Japan. It is preparing a new law on marriage and sterilization.

ACCORDING to the United States National Health Survey the prevalence of blindness is greater among men than among women. For every one hundred blind women, one hundred and eleven men were affected. Nearly twice as much blindness was found among coloured people as among white.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.*

In the present circumstances, proofs of "letters" will not be submitted to correspondents outside Great Britain.

Notes on points in some of this week's letters appear on p. 554. Correspondents are invited to attach similar summaries to their communications.

The Mass of the Universe

I find certain difficulties in connexion with the mass of the universe considered as a finite sphere of radius $4{\cdot}9 \times 10^{23}$ miles and of volume $5{\cdot}2 \times 10^{71}$ cubic miles. Eddington gives the mass of the universe as 10^{22} stars averaging our sun in weight. Taking $2{\cdot}0 \times 10^{27}$ tons as the sun's weight, then the mass of the universe would be $2{\cdot}0 \times 10^{49}$ tons. There are, says Eddington, $1{\cdot}575 \times 10^{79}$ electrons and an equal number of protons in the universe. Assuming the mass of these units to be respectively $9{\cdot}038 \times 10^{-28}$ gm. and $1{\cdot}65 \times 10^{-24}$ gm., then the weight of the electrons must be $1{\cdot}4235 \times 10^{52}$ gm. and that of the protons $2{\cdot}598 \times 10^{55}$ gm.; their combined masses would amount to $2{\cdot}599 \times 10^{55}$ gm. or $2{\cdot}55 \times 10^{49}$ tons, which is a fairly close approximation to the weight of the universe calculated on the basis of stars.

But is not this mass, of the order of $2{\cdot}0 \times 10^{49}$ tons, too low? It would appear to leave out of account the mass of the radiations (photons) that are being poured out by luminous stars into practically every nook and corner of the $5{\cdot}2 \times 10^{71}$ cubic miles of space. Our own sun, we are told, is losing $4{\cdot}0 \times 10^{6}$ tons of matter every second while emitting in the same period of time an equivalent of energy, $3{\cdot}8 \times 10^{33}$ ergs. As the sun is an average representative of the stellar bodies, it follows that the totality of 10^{22} stars comprising the universe is losing $4{\cdot}0 \times 10^{28}$ tons of matter per second, and is emitting in the same time $3{\cdot}8 \times 10^{55}$ ergs.

Hubble, taking a shorter radius ($8{\cdot}23 \times 10^{23}$ miles) and a smaller volume ($1{\cdot}92 \times 10^{63}$ cubic miles) of the universe, gives his estimate of its mean density as $1{\cdot}5 \times 10^{-31}$ gm. of matter per cubic centimetre, that is, about a gram to every $6{\cdot}6 \times 10^{30}$ cm.^{3}, or in more homely weights and measures, about a pound mass in every $7{\cdot}2 \times 10^{17}$ cubic miles. Apart from the energy-equivalent of the matter in space (say $4{\cdot}08 \times 10^{23}$ ergs per pound), what is the mean quantity of the energy of radiations (photons) per unit volume—a cubic centimetre or a cubic mile—of space? Would not the mass of this, added to that of matter, afford a more trustworthy basis for calculating the total mass of the cosmos than a basis which takes into consideration matter alone?

Charles M. Beadnell.

Hollywood,
Egham,
Surrey.

Undoubtedly, the mass of the radiation should be added to the mass of the stars and of the nebulous matter in computing the total mass of the universe. But the general belief is that its contribution is comparatively small—less than 1 per cent of the whole. This is not inconsistent with the figures cited by Admiral Beadnell. With radiation at the rate of 4×10^{28} tons per second, it would take 5×10^{18} seconds, or more than 10^{11} years, to accumulate to 1 per cent of the total mass 2×10^{49} tons. According to cosmological theory, the age of the stars can scarcely exceed 10^{10} years.

Perhaps Admiral Beadnell was thinking in terms of a former time-scale, based on the hypothesis of mutual annihilation of protons and electrons, which allowed an age of 10^{13} years or more. Owing to the discovery of the positron, neutron, etc., this hypothesis (always very dubious) has, I think, no adherents to-day. According to present theories, the source of a star's radiant energy is the transmutation of hydrogen into other elements. This means that less than 1 per cent of the mass of the universe has been, or ever can be converted into radiation. It may be noted that when the mass of the universe is computed from the total number of protons and electrons, no correction for the mass of the radiation is required, since it merely compensates the mass-defect of the nuclei formed by the transmutation.

A. S. Eddington.

Observatory,
Cambridge.

Turnover Rate of Nucleic Acid

Caspersson's work[1] on the nucleic acid metabolism suggests that an appreciable turnover of the nucleic acid present in the nuclei of tissue cells may take place. This fact induced us to determine the rate of turnover of nucleic acid extracted from various organs of rabbits by making use of the method of isotopic indicators applied previously to determine the turnover rate of various other phosphorus compounds.

The labelled sodium phosphate used as indicator was administered all through the experiment in order to keep the activity of the plasma inorganic phosphorus at a constant level. After the lapse of a few hours or days, the nucleic acid was extracted from some of the organs. A slightly modified form of Hammarsten's method[2] was used. The turnover figures, recorded in Tables 1 and 2, were obtained by comparing the specific activity (activity per mgm. phosphorus) of the nucleic acid phosphorus extracted at the end of the experiment with the average specific activity of the cellular inorganic phosphorus which prevailed during the experiment. The value of the activity of the cellular inorganic phosphorus is obtained from that of the tissue inorganic phosphorus after subtracting the share due to the extracellular space of the tissue. The specific activity of the inorganic phosphorus present in the interspaces is

TABLE 1.
TURNOVER OF NUCLEIC ACID IN THE COURSE OF 11·5 HOURS. WEIGHT OF THE RABBIT: 2·4 KGM.

Fraction	Specific activity	Percentage renewed during the experiment
Liver inorganic P at the end of the experiment	100	
Liver cellular inorganic P average during the experiment	69·5	
Liver nucleic acid P	4·0	5·7
Muscle inorganic P at the end of the experiment	18·2	
Muscle cellular inorganic P average during the experiment	10·2	
Muscle nucleic acid P	1·4	13·7
Thymus inorganic P at the end of the experiment	90	
Thymus cellular inorganic P average during the experiment	63	
Thymus nucleic acid P*	3·8	6

* In an experiment lasting 4 hours, the specific activity of the thymus nucleic acid was found to be 2·8 per cent of that of the plasma inorganic phosphorus.

taken to be equal to the specific activity of the plasma inorganic phosphorus. The latter is found, after 4 hours for example, to be 2·5 times as large as the specific activity of the liver inorganic phosphorus. From this figure, and the result obtained that from 100 inorganic phosphorus atoms present in the tissue 3 are located in the interspaces, it follows that from 100 activity units present in the tissue 8 are located in the interspaces and, thus, the specific activity of the cellular inorganic phosphorus at the end of the experiment is equal to 92/97 of that of the tissue inorganic phosphorus. As we have determined the change of the specific activity of the tissue inorganic phosphorus with time, we can calculate the average value of the specific activity of the cellular inorganic phosphorus prevailing during the experiment.

In experiments in which all the labelled phosphate was administered to rats at the start, we found, after the lapse of 24 hours, the specific activity of the liver nucleic acid phosphorus to amount to 28 per cent of the specific activity of the liver phosphatide phosphorus. In a laying hen, after the lapse of 5 hours, the corresponding figure was found to be only 5 per cent.

As seen in Tables 1 and 2, an appreciable turnover of the nucleic acid takes place in all the organs investigated. While, however, all other organic phosphorus compounds present in the liver were found by us to be entirely renewed in the course of a few days, as long as after the lapse of 50 days two thirds of the nucleic acid molecules present in this organ were found to be unchanged. In the muscles, on the other hand, the turnover of the average nucleic acid molecule is more rapid than in the liver or in the thymus. In the brain the turnover rate of the nucleic acid was found to be markedly lower than that of the phosphatides.

TABLE 2.
TURNOVER OF NUCLEIC ACID IN THE COURSE OF 50 DAYS. WEIGHT OF THE RABBIT: 2·5 KGM.

Fraction	Percentage renewed during the experiment
Liver phosphatide P	100
Liver nucleic acid P	33
Muscle phosphatide P	73
Muscle nucleic acid P	93
Brain phosphatide P	77
Brain nucleic acid P	27

All the above data are calculated on the assumption that the inorganic phosphorus atoms incorporated into the newly formed nucleic acid molecules have the same specific activity as the average cellular inorganic phosphorus. It is possible that the penetration of inorganic phosphorus into the nuclei is a slow process and that, correspondingly, the formation of labelled nucleic acid molecules inside the nuclei took place with the participation of phosphorus atoms less active than the average cellular phosphorus. In that case the turnover figures recorded in Table 1 do not represent the proper turnover rates but only their lower limit, and the actual turnover rate of the nucleic acid is still greater than stated above.

In experiments *in vitro*, no exchange was found between the phosphorus of the nucleic acid and that of sodium phosphate, as was to be expected. 100 mgm. thymonucleic acid, kindly presented to us by Prof. Hammarsten, were dissolved in 4 c.c. water, and 0·01 gm. labelled phosphorus as sodium phosphate was added. After shaking the solution for 1 hour, the nucleic acid was precipitated by adding an excess of 1/3 *N* alcoholic hydrogen chloride solution. The precipitate contained only a minute activity. We conclude that less than 1/4000 of the nucleic acid phosphorus was replaced by labelled phosphorus.

Thermal Expansion of Invar

It is well known that invar possesses a coefficient of linear expansion which is much smaller than those of other metals, and that measurement of its expansion over a restricted range in the region of room temperature is a matter of some difficulty. It is therefore thought worth while to direct attention to a method of measuring the coefficient of expansion which is very unusual in that it is unnecessary to know the length of the rod the coefficient of which it is desired to measure.

Joule[1] showed that when a longitudinal tension of F dynes is suddenly applied to a metal rod, there results an adiabatic change of energy $\triangle E$, resulting in a fall of temperature $\triangle T$, given by $\triangle E = J\rho.s.\triangle T = \alpha TF/A$, where α is the coefficient of linear expansion, T is the absolute temperature, J the mechanical equivalent of heat, and ρ, s and A are respectively the density, specific heat and area of cross-section of the rod. It is seen that the quantity $J\rho.s$ is the number of ergs per c.c. which must be imparted to the rod to raise its temperature by 1° C.

Now, invar is ferromagnetic, and, by taking the rod round one half of a hysteresis cycle, a quantity of energy $\triangle E'$ equal to $\int_{-H}^{+H} HdI$, is liberated as heat; this produces a rise in temperature $\triangle T'$ given by $\triangle E' = J\rho.s.\triangle T' = \int_{-H}^{+H} HdI$. If, therefore, we can measure $\triangle T$ and $\triangle T'$, and can calculate $\int_{-H}^{+H} HdI$ from magnetic data, we know α, since it is equal to

$$\frac{\triangle T}{\triangle T'} \cdot \frac{A}{T.F.} \int_{-H}^{+H} HdI.$$

In a recent letter in NATURE[2], we mentioned a new method of measuring the heat generated step by step in a hysteresis cycle. We have now applied this method to an invar rod 0·473 cm. in diameter, purchased from Messrs G. P. Wall, Sheffield. We find that at 7·6° C., the temperature within our cooled solenoid, the calculated value of $\int_{-190}^{+190} HdI$ is 2,984 ergs per c.c., which gives a total deflection of 0·91 cm. with our temperature measuring device. The sudden application of a longitudinal tension of 36·75 kgm. to the rod results in a deflection of 7·21 cm. The ratio $\triangle T/\triangle T'$ is therefore equal to 7·92 and $\alpha = 0{\cdot}411 \times 10^6$ per degree C., correct, in our view, to less than 2 per cent.

Unfortunately, no specimen of superinvar[3] (63·5 iron, 32·5 nickel and 4 cobalt) is at our disposal, but we see no reason why its coefficient of linear expansion should not be obtained in the same way. The method as described above is applicable to ferromagnetic substances only, but it could be modified to deal with non-ferromagnetic materials.

Liberation of Potassium from Muscle by Acetylcholine

POTASSIUM appears to increase the liberation of acetylcholine from frog's heart (Beznak[1]), from the superior cervical ganglion (Brown and Feldberg[2,3]) and from other organs (Feldberg and Guimarais[4]). But it has been found[5,6] that muscles curarized with erythrina, cobra venom, curare, etc., are nearly or completely insensitive to intra-arterial injections of acetylcholine, whereas they react normally to potassium. It may therefore be inferred that if both compounds intervene in the nervous transmission, acetylcholine acts by the intermediate liberation of potassium probably from some organic compound as suggested by Reginster[7] for striated muscles, and Dulière and Loewi[8] for the central nervous system of the frog.

If the sciatic artery of a toad is perfused with potassium-free Ringer solution containing acetylcholine at a concentration of 1×10^{-6} or more, the contracture of the muscles is accompanied by an increase in the concentration of potassium in the liquid flowing from the vein.

Denervated muscles which respond more readily to acetylcholine liberate ten times more potassium than normal muscles, and curarized muscles which do not react to acetylcholine liberate no potassium.

Relationship between the Critical Temperatures, Boiling Points and the Parachor Values of Simple Molecules

IN previous publications[1,2], it has been pointed out that the critical temperatures and boiling points of chemically related substances containing the same number of molecules are linear functions of the parachor values P, and the van der Waals factor b has been shown to be similarly related. It was suggested that the applicability of such a relation to a distinct series was probably due to the similarity of cohesional and configurational functions characterizing a particular group. Recently, an interesting regularity was observed which gives considerable support to this suggestion.

The simple electronic conception of valency pictures the combination of atoms as being due to the preferential arrangements of the outermost electronic sheaths, but the factors giving rise to the known cohesive force which exists between neutral molecules are still a matter of conjecture. It is extremely probable that this cohesive force is governed to a large extent by the arrangement of electrons around the neutral molecules taken as a whole, and that the major part of the cohesive effect is exerted by those electrons which do not participate in a true 'valency bond'. Thus, a consideration of the following molecular types readily gives n, the number of electrons exerting a 'cohesive effect'.

Type	Inert Gas	Halogen acid	Halogen
	$:\overset{..}{\underset{..}{\mathrm{Ne}}}:$	$\mathrm{H}\,\overset{\times}{\underset{\times}{}}\,\overset{..}{\underset{..}{\mathrm{Cl}}}:$	$:\overset{..}{\underset{..}{\mathrm{Cl}}}\,\overset{\times}{\underset{\times}{}}\,\overset{..}{\underset{..}{\mathrm{Cl}}}:$
n	8	6	12

The following table gives the derived equations for the critical temperatures taken from the original paper[1]. It is remarkable that in each case the coefficient of P when divided by the function n gives an almost constant result.

Group	Equation	k (coeff. of P)	n	k/n
Inert gas	$T_c = 3{\cdot}7P - 48$	3·7	8	0·465
Halogen acid	$T_c = 2{\cdot}72P + 130$	2·72	6	0·453
Halogen	$T_c = 5{\cdot}57P - 188$	5·57	12	0·465

A similar regularity exists when the boiling point/parachor equations for a distinct series are considered, and it seems to show that the electrons in a molecule which do not participate in chemical bond formation play an important part in determining the magnitudes of the physical constants.

It is apparent that the general equation, $T_c = 0{\cdot}465\, nP + \text{const.}$ will apply to all the above types of molecules, where n has the previous significance.

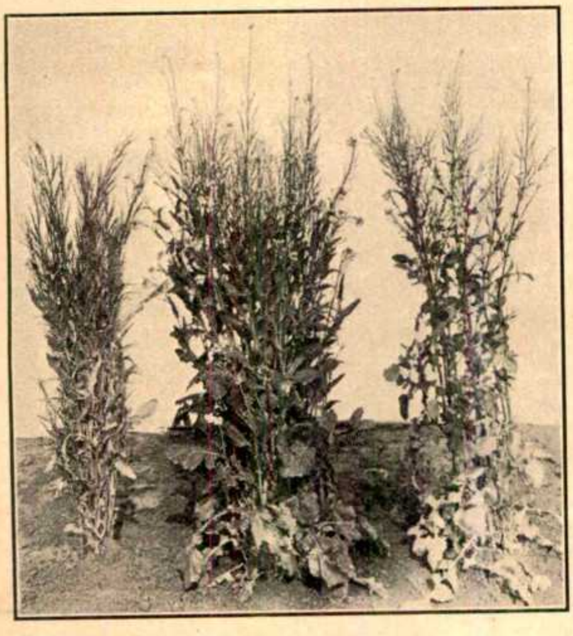
An Apetalous Mutation in Turnip (*Brassica campestris* L.)

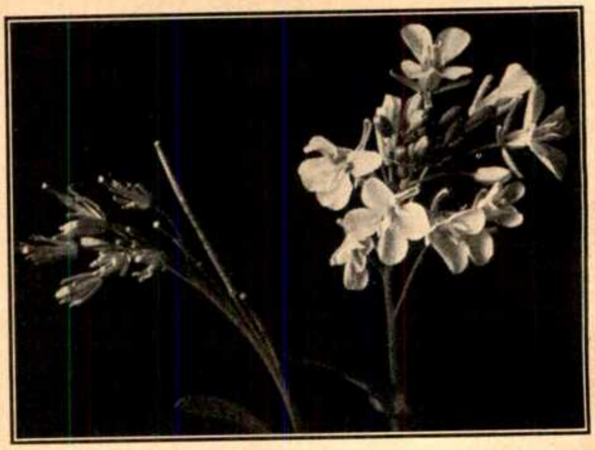
DURING the year 1938–39 a stray plant of Brassica was discovered, in a lucerne field, which looked strikingly different from any of the plants in the very extensive collection of oleiferous Brassicas which were being grown for cytogenetic study. An examination of this erect, compact plant showed that the flowers were devoid of the bright yellow petals characteristic of the genus and that this was the reason for its peculiar appearance. A number of unopened buds were dissected and examined and in every case it was found that the stamens were inserted immediately after the sepals, the whorl of petals being absent. Seed-setting was excellent under conditions of both self- and open-pollination. The chromosome number of the plant was determined at pollen meiosis as $n = 10$, that is, the same as in ordinary turnip, which it closely resembled in morphological characters.

Crosses between the apetalous plant and turnip were made reciprocally, seed-setting in both cases being quite normal. During the current season the crossed, selfed and open-pollinated seeds of the plant were sown. The seeds from the apetalous plant (both selfed and open-pollinated) gave rise to apetalous plants resembling the parent, whilst the crossed seeds gave rise to hybrids which had petals like the turnip parent. Fig. 1 shows the parents and the hybrid and Fig. 2 is a close-up view of the flowers of the apetalous and turnip parents. It is clear from the data above that the apetalous character is heritable and recessive to the petalled condition.



Apetalous form   Hybrid   Turnip

Fig. 1.



Apetalous form   Turnip

Fig. 2.

There is no previous record, so far as I am aware, of the occurrence of any variety in which an apetalous condition is inherited. The only comparable case in literature is that in maize, in which Sprague[1] has reported a mutation in which the glumes were suppressed and the anthers consequently exposed. This mutation in maize is dominant, while in the present case the absence of petals is a recessive character. It is probable that this apetalous plant also arose as a mutation.

The importance of this mutation lies in its possible practical application. Many oleiferous Brassicas are self-sterile and new varieties evolve by mass selection or otherwise rapidly degenerate when grown in the field, owing to cross-pollination. Even if self-fertile forms are obtained, the maintenance of purity of the stocks and their further improvement presents a problem because of the extensive cross-pollination which still goes on. The apetalous plant, however, is not only self-fertile but also self-pollinating and provides an easy means of detecting the hybrids resulting from outcrosses, in its progeny, as such hybrids will possess petals and stand out conspicuously among the apetalous plants. Thus heterozygous plants can be easily rogued and the purity of the strain maintained. Furthermore, the apetalous character, being recessive, can easily be bred into other strains.

As regards the extent of cross-pollination occurring in this plant, it is noteworthy that out of about a hundred plants raised from the seed of the original plant, not a single hybrid was obtained. Preliminary observations this season also show that the amount of cross-pollination must be very low. One row of the apetalous plants was grown between rows of normal plants and daily observations were made of the numbers of visiting insect pollinators.

It was found that these pollinators (chiefly bees) showed a decided preference for the petalled plants and flew over from one row of these to another, neglecting the apetalous plants growing in between.

Studies of the genetics of the apetalous character and its usefulness for practical breeding are in progress.

Relationship of *Gossypium Raimondii* Ulbr.

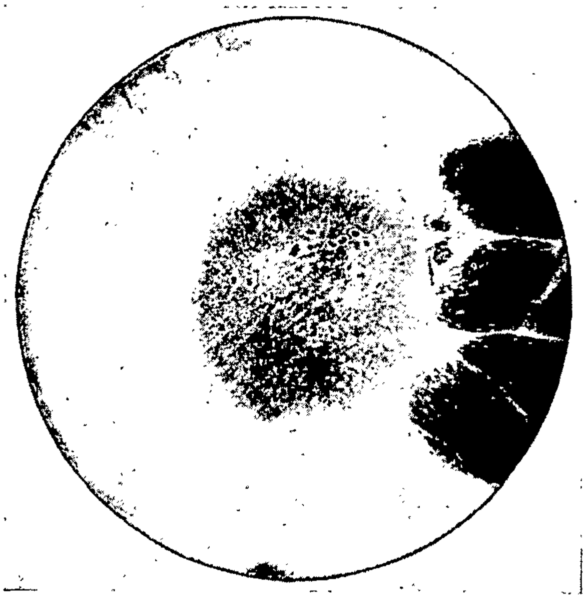
Two notes have recently appeared on the relationship of the wild Peruvian species of cotton *Gossypium Raimondii*, Ulbr.: Hutchinson[1] and Newcombe[2] simultaneously grouped *G. Raimondii* with $2n = 26$ wild New World cottons on somatic counts made by Madoo. They placed it in the sub-group *G. Koltzschianum*, Anderss, *G. Davidsonii*, Kellogg, which it undoubtedly resembles morphologically, the former adding hybridization behaviour.

At La Molina, the chromosome conjugation of *G. Raimondii* at meiosis has shown thirteen bivalents.

In a cross *G. hirsutum*, L. (*U*4) × *G. Raimondii* the meiotic chromosome conjugation shows a mean of 12·57 univalents, 11·65 bivalents, 0·87 trivalents, and 0·125 quadrivalents, and a chiasma frequency of 1·62 per bivalent.

From this data it is suggested that *G. Raimondii* is more closely related to *G. armourianum*, Kearney, *G. trilobum* (*DC*) Kearney, *G. Harknessii*, Brandg., and *G. aridum*, Skovsted, than to *G. Davidsonii*, Kellogg and *G. Klotzschianum*, Anderss.

The accompanying photomicrograph of the conjugation in the hybrid *G. hirsutum* × *G. Raimondii* shows twelve univalents and most of the bivalents.



× c. 1000.

A more detailed study is being put out as an official publication of La Molina Agricultural Experimental Station.

Use of Adsorption Processes for the Detection of "Traces"

METHODS for the detection of a trace of a compound dissolved in water may be made very sensitive if that compound can be concentrated by adsorption at an interface. Thus an almost infinitesimal quantity of grease, adsorbed on a metal or mineral surface, is readily detected by its effect on the displacement of water from that surface by air[1]. Very sensitive tests for copper, lead and cyanide ions were also discovered in the course of an investigation of the basic principles of the flotation process. Though these are not specific, they seem worth recording in illustration of a method that may sometimes be useful.

When a mineral is polished out of contact with air, there is produced a surface from which air is unable to displace water[2]. A pyrite (FeS_2) surface prepared in this way becomes air-avid in a 25 mgm. per litre solution of potassium ethyl xanthate, as a bubble of air pressed against the surface will now adhere to it. One part of CN^- in 2×10^7 parts of water prevents this adhesion.

Sphalerite (ZnS), polished similarly, does not respond to this concentration of xanthate even in the absence of cyanide. However, if there is present 0·006 mgm. lead nitrate per litre as well as the xanthate, the surface does become air-avid, the lead ions acting as a link between the mineral surface and the xanthate ions. Likewise, 0·005 mgm. copper sulphate ($CuSO_4.5H_2O$) per litre induces air-avidity in the presence of sodium di-ethyl dithiocarbamate. Thus one part of lead in 3×10^8 parts of water and one part of copper in 8×10^8 parts of water are detectable. For copper the test is ten times as sensitive as the usual dithiocarbamate test[3].

Angle of Repose of Snow on Solids

IT is well known that the friction of solids on snow surfaces is larger than on ice surfaces. The higher kinetic friction obtained on snow is attributed to the extra work done in displacing and compressing the snow crystals[1]. This may apply to the sliding of a ski or a sleigh on snow. It is, however, common experience that snow also while resting, for example, on the roof of a house or on a metal spade, exhibits a considerable angle of repose.

The extremely small friction of ice surfaces near the melting point is due to lubrication by water at the points of contact between the sliding surfaces. The porosity of snow hinders considerably the establishment of thick film lubrication by the melt. This is demonstrated by the following experiments. The angle of repose of snow and of snow compressed by hand was measured on various surfaces which were at room temperature (about 20° C.). The compressed snow always has the smaller angle of repose (see accompanying table). The 'loose' snow sticks on steel even at an angle of inclination of 90°, while the molten water rises in the snow 'capillaries'.

Base plate	Angle of repose		Coefficient of static friction	
	Loose snow	Compressed snow	Loose snow	Compressed snow
Smooth bakelite	16°	3°	0·29	0·05
Glass	19°	3°	0·34	0·05
Ferrotype	16°	7°	0·29	0·12
Steel	>90°	35°	∞	0·7

The blotting action of the snow, which leaves, in contradistinction to the non-porous ice, at first only a thin adhesive intermediary water film, particularly when melting proceeds more rapidly from the solid base (for example, steel) than from the surrounding air, might become more obvious in an experiment where melting is not involved. A small heap of silica powder flows from a dry glass plate at a small angle of inclination. Addition of a sufficiently small amount of water just to wet the sand heap cements its grains together and cements the sand heap to the glass plate. It sticks to it, even at an angle of inclination of 90°. However, an addition of water, in excess of saturating the sand heap with it, leads to thick film lubrication and makes the sand slide off the glass plate at a small angle of inclination.

Snowfall in the Winter of 1939-40

WHEREAS the great ice-storm which affected a large area in western and southern England on the night of January 27 has been stressed in the various reports which have hitherto appeared on the cold weather, the magnitude of the snowfall seems to have been under-estimated.

Apart from various other snowfalls, there occurred on the very night of the ice-storm an exceedingly heavy fall of dry drifting snow over the whole of south-eastern, eastern, midland and northern England, as well as most of Scotland. In Kent, the Chilterns and East Anglia, the fall on the level was commonly between 1 ft. and 2 ft., and many villages were isolated by huge drifts ; in Lancashire, Cheshire and the Lake District the general fall was between 2 ft. and 3 ft. The fall on the Lancashire coastal plain was apparently the heaviest since February 1900. It is possible, and indeed suspected, that part of the accumulation may have been due to mass drifting from the Pennine uplands to eastward.

The late Mr. Joseph Baxendell, formerly superintendent of the Southport Borough Observatory, has frequently of recent years written to me respecting the scarcity of serious snowfall in west Lancashire, and I cannot but regret that he was not spared quite long enough to see this mighty downfall of snow.

L. C. W. BONACINA.

Hampstead,
London, N.W.3.

Points from Foregoing Letters

THE method of isotopic indicators has been used by L. Hahn and G. Hevesy to determine the rate of turnover of nucleic acid extracted from various organs of rabbits. The rate of exchange is extremely low in the liver ; it is higher in the thymus and in the muscles.

L. F. Bates and J. C. Weston show that the coefficient of thermal expansion of invar may be determined by measuring the changes of temperature which occur when a rod is suddenly stretched and when it is taken through a hysteresis cycle.

It has previously been assumed that the linear relationship existing between the parachor and critical temperatures of chemically related substances is due to similarity of cohesive effect. D. T. Lewis finds that the slopes of these lines vary in a simple manner with the number of electrons in simple molecules which do not participate in the true 'valency bond', and this is put forward by him as evidence that these electrons play a large part in determining the magnitude of the cohesive forces between molecule and molecule.

K. L. Sutherland describes effects on mineral surfaces due to minute traces of copper, lead and cyanide ions. It is pointed out that traces are more readily detected when they have been concentrated by adsorption at an interface.

S. Ramanujam describes an apetalous mutation of the turnip, with $n = 10$, which is the normal number. By crossing with the normal petalled form, the author has shown that the apetalous character is heritable but recessive.

The kinetic friction of solids is higher on snow than on ice, partly on account of the extra work done in displacing and compressing the snow crystals. R. Schnurmann finds the static friction of snow on solids at room temperature still higher, because the porous snow dries up the water arising at the contact with the warmer base, leaving only a thin film between the snow and the base.

L. C. W. Bonacina points out that though the winter of 1939-40 was relatively less remarkable for snow than for frost in the British Isles, there were a number of heavy snowfalls, that of the night of January 27 being very intense in the region lying outside the area of the severe ice-storm and quite unusual in Lancashire.

RESEARCH ITEMS

Acadian French in Louisiana

Results of anthropometric measurements of one hundred young men of almost complete Acadian French ancestry, students of the Southwestern Louisiana Institute, were communicated by H. N. Gould of Tulane University to the Columbus, Ohio, meeting of the American Association for the Advancement of Science, December 27–29, 1939. The subjects were descendants of French settlers deported from Nova Scotia in 1755–60, and belong to a community which has maintained a high degree of cohesion and isolation. Their body measurements do not differ by more than three or four times their probable errors from the corresponding measurements of Old Americans measured by Hrdlička. Such differences as there are point to slightly smaller dimensions in the Louisianians in body, head and face. They are taller on the average than the American soldiers of French descent in the United States army (Davenport and Love). They are superior in height to males in France. In hair colour there are few true blondes, and almost 80 per cent have hair in the range dark brown and brown-black. Red hair is absent. The percentage of light eyes, in spite of the dark hair, is as great as in the Old Americans generally, and the percentage of pure brown eyes is greater. Mixed eyes of irregular blue and brown pattern are relatively less frequent. In so far as this sample is reliable, the Acadian Frenchman of Louisiana is physically "Americanized".

Melanophores of the Cat Fish

G. H. Parker, in a paper read before the Columbus meeting of the American Association, directs attention to the controversy on what constitutes the resting state of the melanophores of the cat fish. It has been customary to compare the colour cells and their nerve fibres with muscles and their motor nerves. Some have regarded the contracted melanophore as being in the active state, and have taken the expanded cell for resting. Others have assumed the reverse to be true, and still others have claimed that both expansion and contraction represent active states. Experiment has shown, however, that none of these hypotheses is correct. A blind cat fish in the dark has no inducement to alter its colour, and fishes from which the eyes had been removed at various stages of darkening remained indefinitely in the condition in which they were at the time when the operation was performed. He concludes, therefore, that all degrees of expansion and contraction are states of rest, and that a state of action is only in evidence when the melanophore is changing from one state to another. The comparison with *skeletal* muscle is, therefore, most inappropriate, and, if such a comparison must be made, it should be between the colour cell and the *smooth* muscle fibre.

Position of Thylacine or Tasmanian 'Wolf'

Fifty or sixty years ago the marsupial wolf (*Thylacinus cynocephalus*) was a common Tasmanian animal, feeding upon small marsupials and sheep. As a consequence of the destruction of the flocks of settlers, the Government of Tasmania paid up to £1 a head for its slaughter, with the result that it was exterminated in the neighbourhood of settlements and found safety only in the wild western parts of the island. The threat of extermination resulted in prohibition of the export of the animal and its complete protection in the island. Unfortunately a new roadway linking Hobart with Queenstown has penetrated the wild country where the Thylacine appears to be making its last stand, and this adds a new threat to its survival. In order to estimate the present-day position of this rare creature, surveys of its territory have been made, and in one part it is reported from observation of tracks that "it was not unreasonable to estimate that the district contained as many as half a dozen pairs". M. R. S. Sharland considers that the creation of a sanctuary adjacent to the West Coast Road, including some 300,000 acres of land of varied character unsuitable for agricultural development, would best meet the needs of the Thylacine and other mammals (*Proc. Roy. Zoo. Soc. N.S.W.*, 20 ; 1938–9).

Black and the Striped Marlin

A detailed account of measurements and external features of these gigantic fishes is given by William K. Gregory and G. Miles Conrad (*Bull. Amer. Mus. Nat. Hist.*, 76 ; 1939). Microscopic examination of the gonads proves that there is little or no difference in external body form between the sexes of the black marlin, both male and female having been secured. A summary of the characters of the body-forms of the striped marlin, *M. mitsukurii*, the Atlantic blue marlin, *M. nigricans ampla*, and the Pacific black marlin, *M. nigricans marlina*, shows that although there is intergradation in all features of the body-form, there are proportional tendencies which when considered in groups serve to aid in separating them. They are generally easily distinguished by colour and other qualitative differences upon gross examination. The black marlin differs from the striped and the blue marlin in the fact that the pectoral fin, when adducted, remains in the horizontal position, whilst in the others it can be brought up flat against the side of the body.

Effect of Rubbing on Leaf Respiration

L. J. Audus has now extended his earlier observations upon cherry laurel leaves to cover a fairly wide series of leaf types, and in almost all cases has found a well-marked increase in the rate of evolution of carbon dioxide as the result of gentle rubbing of the leaf tissues (*New Phyt.*, 38, 284 ; 1939). In the case of softer mesomorphic leaves, they were held between the thumb and forefinger and then gently bent in different directions. Treatments which produced no visible damage were sufficient to produce a very marked increase in respiration. These results obviously have very considerable significance in connexion with many experimental investigations in which isolated leaves have been used and, necessarily in many cases, handled freely during the setting up of the experiment. They recall the earlier observations of J. M. Janse upon the marked effects produced upon the further growth of the roots of seedlings by a very slight amount of handling (*Proc. Koninkl. Akad. van Wetensch te Amsterdam*, 29, 834 ; 1926).

Maize Breeding

J. PHILP (*Bull.* 202, Min. Agric., Egypt) has shown that the F_1 of the inbred lines of maize derived originally from America and from native sources shows increased yields up to 27 per cent above the parental lines. The practical problems pertaining to Egypt's conditions are discussed, and it would seem that a great improvement in the crop yield is possible by this method.

Raspberry Mosaic

R. V. HARRIS (*J. Pom. and Hort. Sci.*, 17, 318; 1940) describes experiments in which mosaic disease was transmitted from nine varieties of European red raspberry and one American variety (Bath's Perfection) to the European variety Baumforth's *B*. All attempts to transmit the disease by mechanical means, such as injection with juice from infected canes, failed, but successful transmission was achieved by several different kinds of grafting. The symptoms induced in the test variety were in all cases recognizable as one of two distinct types, or as a combination of the two. They are ascribed to two different virus groups referred to as mosaic 1 and mosaic 2. Mosaic 1 always produced mild leaf symptoms of the same type, from whatever variety the infection was derived. It produced similar symptoms on two other varieties, Lloyd George and Reader's Perfection. These features are characteristic of a simple disease due to a single virus with a comparatively limited varietal distribution. Mosaic 2 comprises two or more diseases inducing leaf symptoms which are identical, but varying in severity from mild to very severe. Different varieties varied widely in susceptibility to mosaic 2, and masking of symptoms occurred on some varieties. In one case, Lloyd George, leaf symptoms were entirely absent from artificially infected canes, whilst with Preussen and Red Cross, symptoms were suppressed for a season, or limited to single leaves or canes. It is noted that great similarity occurs between mosaic 1 and mosaic 2, and the American diseases yellow mosaic and green mottle mosaic respectively.

Rocks of Mount Everest

IN the Records of the Geological Survey of India, 1939, pp. 171–188, L. R. Wager gives an interesting account of the Lachi Series of North Sikkim and the age of the rocks forming Mt. Everest. From Everest to North Sikkim a thick comformable series of sediments lying below the Jurassic and Cretaceous rocks of the Tibetan plateau, and often much metamorphosed and injected by granite, has now been distinguished and in part mapped. First there is the Tso Lhamo series, with fossils indicating a Triassic age. Below them is the Lachi series, an upper horizon of which contains an Upper Permian brachiopod fauna. Below this again is the Mount Everest limestone series of Carboniferous or Permo-Carboniferous age. These calcareous sediments form the actual summits of Mt. Everest and of several surrounding peaks. Towards the base of the series the limestone becomes more pelitic and is much metamorphosed by thick sheets of granite and granite-gneiss. The underlying rocks, though much injected by granite with formation of banded gneiss, are shown to consist of about 4,000 feet of dominantly pelitic sediments called the Mount Everest pelitic series. No fossils have yet been found in these rocks, but since the lie conformably below the Mount Everest limeston series they are probably of Upper Palæozoic age. I is clear that in the eastern Himalaya sedimentatio in the Tethys geosyncline began early—probably i or before Carboniferous times—and continued wit no serious interruption until the Eocene.

Mechanism of Wurtz Syntheses

THE study of some condensation reactions b sodium (A. V. Morton, J. T. Massengale and G. M Richardson, *J. Amer. Chem. Soc.*, 62, 120, 123, 126 129; 1940) leads to the view that the Wurtz product the dimer, is reached by way of an intermediat organometallic compound, for example, benzyliden disodium and benzyl sodium, there being no need t postulate any other special mechanism, although i is possible to superimpose on this view an ioni mechanism (organosodium compounds are salts) or free radical mechanism, and side reactions and de compositions may occur. Assumption of an inter mediate free radical provides at present a convenien explanation for some of the products. In the experi ments it is shown, for example, that no decane i formed prior to the formation of amylsodium in th reaction between amyl chloride with sodium, th amylsodium then reacting with addition of amy chloride. Ortho-phenyldiphenyl and diphenyl ar not metallated by phenylsodium but are by amyl sodium. Several other reactions are described in th papers.

Criteria of Moving Star Clusters

W. M. SMART has published a paper entitled "The Scorpio-Centaurus Cluster (The Southern Stream)" which disproves a view held for about a quarter of a century on a number of *B*-type stars, lying betwee galactic longitudes 210° and 330°, forming a movin cluster (*Mon. Not. Roy. Astro. Soc.*, 100, 2; Decembe 1939). If the Southern Stream is a real movin cluster, it should be possible to apply other criteri than those previously used to substantiate th hypothesis. Smart's procedure is similar to tha adopted in an earlier paper (*Mon. Not.*, 441; 1939) One very important result of the method is th determination, for each star of the so-called stream, of its own appropriate value of *K*, assuming that the existence of the stream is established. Rasmuson's list of 160 stars is used as the basis of the calculation in deriving the position of the convergent point; the equatorial co-ordinates of this (91°–37°) are close to the solar antapex. The stream velocity is derived by means of the observed total proper motions and spectroscopic parallaxes on the assumption that the stars form a moving cluster, and is found to be 18·8 km./sec. The application of the absolute magnitude criterion shows that the results are not hostile to the assumption of the stars in Rasmuson's list belonging to a moving stream, but are on the whole inconclusive regarding the constitution of the cluster. With the above stream velocity, the calculated radial velocity of each star is compared with the observed radial velocity, and if the stars move in a cluster the difference should theoretically be the *K* term. The result of the investigation is conclusive against the view that the stars under discussion form a moving cluster. In fact, the 'stream-velocity' is simply the solar velocity, and the 'convergent point' is the position of the solar apex.

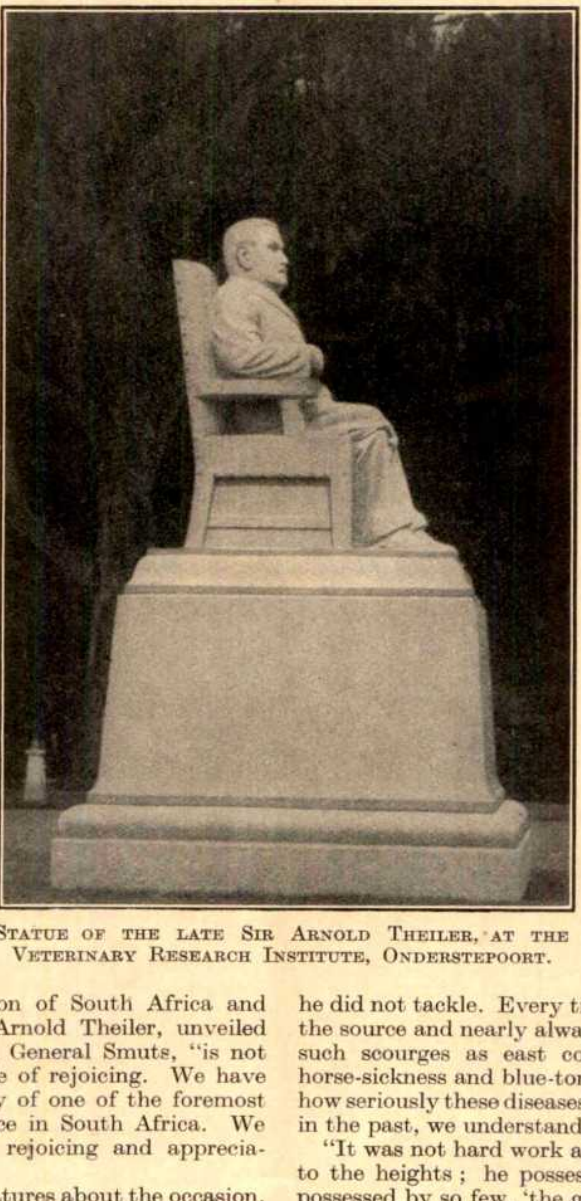
MEMORIAL TO SIR ARNOLD THEILER

SIR ARNOLD THEILER, founder and first director of the Veterinary Research Institute at Onderstepoort, near Pretoria, South Africa, died in London on July 25, 1936. His great services to veterinary science were widely recognized during his lifetime and many rewards and honours were showered on him. He received no less than seven honorary doctorates. Of other great distinctions may be mentioned his election to the Paris Academy of Sciences, the award of the Laveran Gold Medal, the Budapest Gold Medal, and the Gold Medal of the Royal Agricultural Society of England. He was an honorary or corresponding member of some twenty scientific societies.

After his death the country of his adoption bestowed an even greater honour on him than any he had received during his life. The Government of South Africa decided to erect a monument to his honour at the institute which he had founded

On Wednesday, November 15, 1939, before a large and distinguished gathering, including the members of the Diplomatic Corps, Cabinet Ministers, heads of Government Departments, many scientific workers and other prominent citizens, General the Right Hon. J. C. Smuts, Prime Minister of the Union of South Africa and a personal friend of Sir Arnold Theiler, unveiled the statue. "To-day," said General Smuts, "is not a day of mourning, it is one of rejoicing. We have come to honour the memory of one of the foremost men in the history of science in South Africa. We are filled with a spirit of rejoicing and appreciation.

"There are some special features about the occasion. Firstly, this is the only occasion on which a monument has been erected to a great man in the Union by the South African Government. Hitherto we have always left it to friends and admirers to collect funds for a memorial, but Sir Arnold seemed to this Government and the previous Government to be an outstanding case where an exception should be made. He had done such great service that we felt we were justified in erecting a memorial on behalf of the entire nation instead of merely of a group."



STATUE OF THE LATE SIR ARNOLD THEILER, AT THE VETERINARY RESEARCH INSTITUTE, ONDERSTEPOORT.

Secondly, said General Smuts, South Africans had been prone to honour men who had held high public posts in their country—statesmen, soldiers and outstanding public men. Sir Arnold, however, had not been in the public eye, he had not occupied a high position. He had been a man of science pure and simple, and had belonged to a branch of science which had no high honour attached to it—veterinary science. "But," continued General Smuts, "this veterinary doctor made himself, this institute, this country famous all over the world. More than any other man he has put South Africa on the science map of the world."

General Smuts touched on the history of Theiler. He mentioned how General Botha had encouraged the young Swiss veterinarian and how, realizing the vast importance of scientific work, he had sponsored the grant for the erection of the institute at Onderstepoort.

"There are many young men to-day who must have a vivid recollection of Sir Arnold Theiler's great personality. He was sincere, straight, powerful, enthusiastic, devoted to his work. Many books have been written on his scientific discoveries. There is not an animal disease of any importance which he did not tackle. Every time he found out the cause, the source and nearly always the cure. He worked on such scourges as east coast fever, red-water fever, horse-sickness and blue-tongue. And when we realize how seriously these diseases have retarded our progress in the past, we understand what a benefactor he was.

"It was not hard work alone which took Sir Arnold to the heights; he possessed that added something possessed by so few, 'the genius of insight'. And yet, in spite of his greatness, he was a simple soul; he lived and worked for his profession.

"We should be proud of this institute of Onderstepoort which he built up," said the Prime Minister. "The men here merely do their jobs. They are not politicians and I hope they never will be. They are here to carry on the scientific tradition of devotion to duty which he began."

The statue, made in granite quarried near Pretoria, was sculptured by Mr. Coert Steynberg.

RECENT RESEARCHES IN AMERICAN ARCHÆOLOGY

AMONG numerous evidences of increased interest in the United States of America in the antiquities of the continent and the origin, character and cultures of its earlier inhabitants is the fact that research in branches of study bearing upon such problems is no longer confined mainly to the more influential and populous intellectual centres, with their widely known and strongly supported universities, museums and other learned bodies. Local research, and even investigations implicating extended ramifications, are now appearing with regularity in the departmental studies of universities and academic institutions in the outlying and remoter States. Financial support, however, at least so far as concerns investigation in the field, is not always readily to be obtained, and various economies have to be practised. If these affect publication, as indeed frequently happens, results of importance may be overlooked, especially in Great Britain, where, unfortunately, it is sometimes difficult for archæologists to keep fully abreast with the progress of such research in America. Owing, however, to the financial limitations to which reference has been made, an index to activity in research, naturally not in archæology only, which alone is under consideration here, is afforded by the reports of bodies administering the various funds, to which scientific research in America is in the fortunate position of being able to look for support. Among such bodies, the American Philosophical Society takes a prominent place, owing to the value of the funds under its control, while the accounts of the researches it subsidizes which appear in the Year Book*, brief as they are, are a valuable guide to the trend of scientific investigation in widely extended fields throughout the academic world of the United States.

From this point of view, the following notes on recent archæological investigations, extracted from reports in the Year Book, will be of interest.

The discovery of characteristic stone artefacts attesting the existence of an early and primitive hunting people, who from the association of their relics, it is evident, were contemporary with a fauna pleistocene in character and now extinct—a people to whom the distinguishing name of Folsom man is assigned—has naturally given rise to inquiry as to how and by which route this culture and other cultures, apparently even earlier in time, reached the south-western States, the region of their discovery. The hypothesis that their penetration of the south-west was from the north, and took place in the Pleistocene age, by way of an ice-free corridor, has naturally stimulated investigation with the view of finding traces of the distinctive culture of Folsom man in the more northerly regions of the continent. The search has not been without result, notably in the work of Dr. F. H. H. Roberts in Canada. An investigation on similar lines was undertaken by Wesley L. Bliss, of the University of New Mexico, by whom an archæological and geological reconnaissance has been carried out in Alberta, the Mackenzie Valley, and on the Upper Yukon, with the financial assistance of the American Philosophical Society.

In the preliminary report the purpose of the investigation is stated to be "to tie in, if possible, early cultural and culture complexes in relation to glacial chronology". It followed on investigations already carried out in 1937 with the co-operation of the University of Alberta in which Yuma points, belonging to a south-western culture related to the Folsom culture, were located in eastern Alberta, and cultural affinities and contacts were demonstrated with British Columbia and Wyoming or the west coast, while abalone shell-pendants indicated connexions with the Californian coast. In the following season, geological investigations showed that all the area covered by the expedition along the Sikanni, Nelson and Liard Rivers of the Mackenzie River basin had been glaciated by Keewatin ice. Evidence of cave occupation by man was found near Blue Fish Lake, north of the Nahanni Butte, where ash layers overlay the blue clay deposited during glaciation, while information was obtained of smoke-darkened walls in two others. Search for evidence of man below the clay, which would prove human priority to the Keewatin advance of the ice in this region, is obviously desirable. The existence of an ice-free corridor from Bering Straits eastward to the Mackenzie delta was inferred from the absence of any evidence of glaciation in the valley of the Little Bell River, a tributary of the Yukon. Near Neon Lake, at the top of the pass, two terraces above the lake yielded artefacts comparable to the Pleistocene Lake Mohave artefacts of California and closely resembling those from the lowest cultural stratum of Borax Lake, California, which antedate the Folsom culture.

On returning to Alberta, field work was resumed, and four Yuma sites were found near Cereal, and two Folsom sites examined in western Saskatchewan. Of these, one near Mortlach is situated on the Altamont moraine and definitely dates Folsom as post-Wisconsin. An isolated flaked microlithic point from eastern Alberta is identical with points from the campus of the University of Alberta and also with those of the dune dwellers of Gobi in Central Asia.

Geographical conditions show that the great river basins of the north-west were more probable routes of migration from Asia than the rugged Alaskan and British Columbian coasts. Mapping of the Illinoian and Wisconsin moraines indicates an open corridor between the mountains and the continental glaciers in these periods.

Prior to this reconnaissance, nothing was known archæologically of the regions covered.

Recent archæological surveys of the south-western United States have been directed to the classification of the cultures found on occupation sites. Of the four basic cultures recognized, little is known by excavation of the Patayan culture, which centres in the Colorado River valley below Boulder Dam. In fact, north-western Arizona, to which this culture belongs, has been a blank place on the archæological map.

In the summer of 1938, an expedition of the Museum of Northern Arizona under Lyndon L. Hargrave, field director of the Museum, with the assistance of a generous grant from the Penrose

---

* The American Philosophical Society. Year Book, 1938. Pp. 407. Philadelphia: American Philosophical Society, 1939.)

Fund, made an intensive study of sub-cultures of the Patayan culture, excavating a site seven miles north of Williams, Arizona, which consisted of a large masonry fort and seventeen earth lodge sites. A preliminary conclusion, pending further analyses, establishes the existence of the Cohonina Branch of the Patayan culture, differing essentially from the Hohokam of the south and the Pueblo to the east. A relationship to the people of the Colorado to the west is suggested.

The Cohonina lived a semi-sedentary life, part agricultural, part food-gathering. Their homes were surface structures built of perishable material, earth lodges, of which the detailed architecture is difficult to trace. Much charcoal was collected, which, however, has as yet yielded no dendrochronological evidence. Ceramic types date occupation at about A.D. 700 and A.D. 1100, the fort with its massive masonry belonging to the later period of occupation. A special projectile point was used to which the name "Cohonina point" has been given. Few ornaments were used, none of shell. The pottery belongs to the San Francisco mountain gray ware; and from its distribution it is possible to fix the extension of the Cohonina Branch—the area between the Little Colorado River on the east and the escarpment of the plateau on the west, and from the Grand Canyon on the north to the San Francisco volcanic field in the south.

An investigation of primitive Indian agriculture in the south-west by Edward F. Castetter, of the University of New Mexico, throws light on the crops grown anciently in this region. A preliminary survey was made of the technique, crops and implements among Mohave, Yuma, Cocopa, Maricopa, Papago, Pima, and a number of Pueblo groups. The ancient crops were maize, beans, pumpkins, cotton, tobacco and gourd. In addition, the Colorado River tribes sowed several species of grasses. The Pueblo peoples had a much greater variety of corn and beans than the peoples of the Gila and Colorado Rivers, who had only four—yellow, blue, white and speckled, all corn of the flour type. The pumpkins were *Cucurbita moschata*. It was found that agriculture could not be investigated adequately without knowledge of ritual, the two being inseparable; but it was difficult to obtain information owing to the secrecy of the Indians, especially the Pueblo, on such matters.

BIOLOGY AND SYSTEMATICS OF THE SARGASSUM WEED

MATERIAL for research on the floating Sargassum vegetation of the western North Atlantic was collected in connexion with a series of hydrographic cruises to the central American seas on the research ship *Atlantis*, sponsored jointly by the Woods Hole Oceanographic Institution and by Yale University (under the auspices of the Bingham Oceanographic Foundation), a special surface net being used which was designed to gather floating weeds from the sea surface on a quantitative basis, and the results of the researches have now been published*.

This net has been in actual operation on the surface of the Sargasso Sea and of the central American seas for a total cumulative towing length of nearly 7,000 nautical miles, and as a result of this towing more than 4,700 pounds of pelagic weeds have been sorted and weighed on board. Experimental evidence shows that these weeds do not occur in any quantity at any significant distance below the surface.

In the taxonomic discussion a key is given for the identification of the main types of floating Sargassum weed, illustrated by a number of silhouettes. The author concludes that the fixed, more or less distinct, external forms in which the truly pelagic weeds occur represent only phenotypic variations of not more than two separate species, *S. natans* and *S. fluitans*. Even the distinctness of these two species, although probable, is not established entirely without doubt.

The quantitative estimates show that floating weed is scarce in the Caribbean and Cayman Seas and practically absent from the entire southern half of the Caribbean itself, whilst in the north-western region of the Gulf of Mexico a secondary accumulation of apparently deteriorating weeds in considerable abundance was observed over a wide area. The chief region for thriving pelagic weeds was entirely outside the central American seas in that part of the North Atlantic designated as the Sargasso Sea.

The distribution, as shown in these results, confirms the previous hydrographic conclusions, that the failure of the drifting flora to penetrate northward across the Caribbean agrees with the assumption that the Caribbean surface water is mainly derived from the south-east via the north equatorial current and not from the Sargasso Sea itself. The accumulation of floating weed in the north-western part of the Gulf of Mexico must be interpreted as a result of pure wind drift, due to prevailing easterly winds moving the weeds in relation to the water; this accumulation could scarcely take place in the presence of a significant tendency to outward movement of the surface water towards the Straits of Florida.

Up to the present time, no benthonic fixed stage is known of the two species *S. natans* and *S. fluitans*, and it has been a controversial subject as to whether these weeds grow vegetatively to any great extent in the floating state. Recent authorities increasingly favour the theory that such growth does take place, and the present work shows conclusively that these weeds grow and prosper for years without any sexual reproduction; and further, there can be no conceivable source and process of annual renewal of pelagic Sargassum vegetation from benthonic flora which could possibly maintain the floating vegetation in its observed abundance with an average duration of the pelagic state of the individual plants to be reckoned in less than decades. One fertile plant attached to a drifting piece of wood was obtained which was otherwise indistinguishable from sterile representatives of the pelagic *S. fluitans*, the only one ever found and of great importance in showing the form of the sexual phase, as it will now be possible to search for a known fixed form.

---

* "Quantitative Observations on the Pelagic Sargassum Vegetation of the Western North Atlantic. With Preliminary Discussion of Morphology and Relationships". By Albert Eide Parr. *Bull. Bingham Oceanographic Collection*, Peabody Museum of Natural History, Yale University, 6, Art. 7. Dec. 1939.

It is thus firmly maintained, supporting Winge (1923) and others, that "the pelagic *Sargassum* of the Sargasso Sea, apart from its marginal zones, is probably an essentially self-sustaining unit with a potentially infinite longevity and a very long normal expectancy of life for its individual plants, receiving (at most) only a very slight annual contribution from benthonic vegetation merely sufficient to compensate for its own loss by a slight excess of mortality over vegetative growth increment, suffered mainly through a continually occurring chance return of some of its members to the dangerous marginal zones from which a corresponding recruitment of freshly detached plants which have escaped its hazards are received in exchange."

The significant fact remains that no fixed benthonic stage is yet known of either of the two predominant types of floating Sargassum weed of the Sargasso Sea, namely, *S. natans* and *S. fluitans*. It seems that it must be concluded that here we have an essentially self-sustaining community of plants in which the pelagic existence has become secondarily normal, and which are able to maintain and multiply themselves indefinitely by mere vegetative growth, mechanical fragmentation and irregular partition of the individuals through disintegration from the basal end.

RECENT AMERICAN INVESTIGATIONS IN EMBRYOLOGY

AN interesting paper of practical importance in orthopædic practice, entitled "The Functional Results of Muscle Transposition in the Hind Limb of the Rat", was read by Prof. R. W. Sperry at the Columbus Meeting of the American Association last December. The muscles operating the hind foot of this animal were transplanted in reverse, with the result that both reflex and voluntary movements of the hind limb were also reversed. Motion pictures showed that even after a year's trial of the new arrangement, there was no adjustment, and although the muscles worked the limb, the motor nerve patterns for limb co-ordination were on the old basis. Unfortunately the author does not state the names or number of the transplants.

Papers on experimental embryology related to the early development of the sea urchin, *Arbacia punctulata*. Profs. W. C. Allee and Asher J. Finkel, starting from the observed acceleration in cleavage-rate due to density of egg population and suspecting that some growth-promoting substance was responsible, carried out a series of experiments at Woods Hole with the intention of finding out more about the stimulating factor. They did not succeed in determining the chemical nature of the substance or substances; but their experiments showed that an extract from *Arbacia* eggs, even in "extremely dilute concentrations, can accelerate the early development of *Arbacia* eggs to a significant degree over that of untreated but otherwise similar eggs". They suggest that "undercrowding is as real in its effects as overcrowding".

Miss Ethel Browne Harvey studied the role of the nucleus and the cytoplasm in *Arbacia* eggs. Unfertilized eggs, broken into half eggs by centrifugal force, give a nucleated and a non-nucleated half. Both halves can be fertilized, or activated artificially. In the former case two plutei are produced; in the latter, the nucleated half becomes a pluteus, the non-nucleated half a blastula only. Fertilized eggs behave differently. A half containing both pronuclei forms a blastula, or at most a defective pluteus. A non-nucleated half, although its cytoplasm is affected by fertilization, does not even cleave, but the cytoplasm may make an attempt to produce asters.

The author calls the development of the non-nucleated half of the artificially activated but unfertilized egg "parthenogenetic merogony". But since this half develops to the blastula stage only, it would appear that a nucleus is essential for the *differentiation* of the cells, though not for their mere multiplication.

Prof. Robert Chambers and E. L. Chambers found that fertilization of the egg in *Arbacia* could be arrested by immersing the egg immediately after insemination in a solution of potassium chloride, the strength of which is not stated. The return of the eggs so treated to normal sea-water more than an hour later causes resumption of activity of the sperm and subsequent normal development.

Two papers on transplantation of embryonic limb buds in birds were read by Prof. H. L. Eastlick. In the first set of experiments the chick embryo was the host, and duck, chukar partridge, quail, guinea fowl and turkey were the donors of the grafts. Both leg and wing were employed, transplantation being effected on embryos two to three days old. The egg was then re-sealed and put back in the incubator for further development. Fifteen per cent of the embryos hatched with the graft as a fifth limb. These grafts retained the structural characters of the donor species, except in a few cases where a partial merging of skin characters of donor and host occurred. Thus a duck leg graft formed a webbed foot, the feathers of which failed to develop after a poor attempt to do so; they were followed by a second growth of host feathers. In other cases the graft limb grew at first but was later resorbed.

According to a second paper the birds mentioned above were used as hosts, but did not prove as successful for this purpose as the chick. Although the graft retained many of the characters of the parent bird, the age and extent of the graft affected the result. In particular, a graft removed with a portion of the neural crest developed feathers of the same colour as the graft's parent, whereas a graft cut laterally so as not to include the neural crest partook of the colour characters of the host. Grafts from white silky bantams, the feathers of which have no hooklets on the barbules, retained this character when transplanted to White Leghorn or Barred Plymouth Rock hosts. Prof. Eastlick described and illustrated some of his results in a brief communication published in NATURE of August 26, 1939, p. 380.

ROAD RESEARCH

THE work of the Road Research Laboratory during the year ended March 31, 1939, is described in the annual report now obtainable*.

An important event recorded is the enlargement of the site of the Laboratory by sixteen acres, which has made possible the construction of a special skidding track 2,000 ft. long, providing facilities for investigating the causes of skidding under more favourable conditions than exist on the roads and forming a useful calibration surface for the several machines used by the Laboratory and by the Ministry of Transport. A notable feature of the report is its indication of the way in which the research work is now evolving from the purely laboratory stage into the large-scale practical demonstrations of the road engineer. Examples of this development which are to be found in the report include the full-scale tests on the use of acid to reduce the slipperiness of smooth concrete surfaces, the treatment by chemicals of ice-bound concrete surfaces and durability tests on bituminous and asphaltic binders. In co-operation with the Timber Development Association extensive practical trials are proceeding with the view of improving the skidding resistance of wood-block surfaces, while other large-scale investigations have led to a better design of cast-iron surfacing by which the sideway force coefficient has been increased from about 0·25 to 0·45.

Soil mechanics in several important aspects continues to be developed, and experience of soil surveys undertaken in conjunction with the Ministry of Transport prior to the building of experimental roads has confirmed the view that useful and often essential information can be obtained in this way. As knowledge of subsoil conditions accumulates, it is reasonable to expect that the value of such soil surveys, preliminary to construction, will become progressively greater. The principal addition to the equipment of the Soil Mechanics Laboratory during the year has been an apparatus for obtaining undisturbed samples of soil, which operates a sampling tool by means of a double-acting hydraulic ram. After a hole has been drilled in the ground to the required depth, the tool is lowered into position and pressed home by the 10-ton ram. Incorporated in the tool-head is a relief valve which permits air or water to be expelled. The samples are tested in a new type of consolidation machine which also has been designed and constructed at the Road Research Laboratory during the year. An illustration shows a machine of a simple lever-loading type in which the specimen is held rigidly against a steel ball, the deformation being indicated on a dial gauge. In this department of the work, standard tests are being developed and the mechanical and physical properties of soils are being investigated, particularly in relation to the shrinkage of stabilized soils and the principles of soil compaction.

As already indicated, road surfacings receive a large share of attention. The report gives further details of the system of recording progressive changes in roads by means of the recently developed surface texture prints. These, as described in NATURE of January 6, p. 40, are a form of offset prints made on sheets of paper by means of a printing roller run over a small area of the road surface.

SEVENTY YEARS AGO

NATURE, vol. 1, April 7, 1870

Natural Science at Cambridge

WE have heard so much recently of the long-delayed determination of Cambridge University to apply itself in earnest to the cultivation of Natural Science, that the information in the following paragraph must be a blow to those of its friends who hoped to see that it was entering on a new course: "The Syndicate appointed to consider the means of raising the necessary funds for establishing a Professor and a Demonstrator of Experimental Physics, and for providing buildings and apparatus . . . have made a report to the Senate, in which they state that they have addressed a communication to the several colleges of the University, to inquire whether they would be willing . . . to make contributions from their corporate funds for the above-mentioned objects. The answers of the several colleges, except that of King's, which has not yet been received . . . indicated such a want of concurrence in any proposal to raise contributions from the corporate funds of colleges, by any kind of direct taxation, that the Syndicate felt obliged to abandon the motion. . . . They confined their attention, therefore, to the means of raising sufficient funds only for carrying out the recommendations of the Physical Science Syndicate in their report dated Feb. 27, 1869. These were to provide the stipends of a Professor of Experimental Physics, of a Demonstrator and an attendant, requiring altogether a sum of 660 *l.* per annum; also to provide a capital sum of 5000 *l.* for a new building, and 1300 *l.* for apparatus. The Syndicate are of opinion that these sums may be raised from the ordinary sources of revenue of the University."

The Rotundity of the Earth

A RECENT number of the *Field* contains an account of a very amusing investigation which has been recently conducted on the Bedford Level to settle the question whether the earth is a globe or not! It appears that a Mr. Hampden threw out a challenge by which he offered to pay 500 *l.* to anyone who would prove the rotundity, which challenge has been taken up by Mr. A. R. Wallace, who has lodged a similar sum with the Editor of the *Field*. To test this point, six miles of the Bedford Level were used, three signals, each 13 feet 4 inches above the water level, being put up three miles apart. Mr. Wallace asserted that if he were correct the central signal would appear elevated about 5 feet above the line joining the other two; Mr. Hampden holding, of course, that they would all be in the same straight line.

Although the diagrams of what was seen by the telescopes used at both ends, and acknowledged to be correct by Mr. Hampden and his associate, show the central signal more than 5 feet above the line of the two extremes, "these gentlemen coolly claim the victory, and threaten to bring an action against the Editor of the *Field* (who was appointed unpire by Mr. Hampden himself) for fraudently deciding against them."

WE hear from Edinburgh that there is much excitement amongst the supporters of the Lady Medical Students, on account of the Professor of Chemistry refusing to accord one of the Hope Scholarships to Miss Edith Pechley, who, by the number of marks gained, is entitled to a junior scholarship.

Royal Photographic Society, at 7 p.m.—W. W. Nicholas: "Bird Watching with Still and Cine Camera".

Pharmaceutical Society, at 7.30 p.m.—Dr. C. H. Hampshire: "Pharmacopoeia Revision".

Thursday, April 11

Linnean Society of London, at 5 p.m.—General Meeting.

At 5.25 p.m.—(Joint Meeting with the Association for the Study of Systematics in relation to General Biology): A Symposium on Phylogeny and Taxonomy. (Speakers: J. S. L. Gilmour, Dr. O. W. Richards, Dr. T. A. Sprague, Dr. E. I. White.)

Council for Education in World Citizenship (at Somerville College, Oxford), at 8.15 p.m.—Dr. Gilbert Murray: "World Citizenship, the Growth of an Idea" (Inaugural Address).*

Friday, April 12

Royal Aeronautical Society (at the Institution of Electrical Engineers), at 6.30 p.m.—Sir Alan Cobham and Marcus Langley: "Flight Refuelling".

Society of Chemical Industry (Joint Meeting of the Chemical Engineering Group and the Food Group), at 8 p.m.—T. W. Jones: "Chemical Engineering Problems in the Canning Industry", followed by a general discussion. (Speakers: Osman Jones and F. D. Farrow.)

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Temporary Pathologist—The Secretary, Hospital for Consumption, Brompton, S.W.3 (April 10).

Chemist and Bacteriologist—The Water Engineer, 70 Park Lane, Croydon (April 12).

Technical Assistant in the County Land Drainage Officer's Department—The Clerk to the Essex County Council, County Hall, Chelmsford (April 13).

County Librarian—The Education Officer, County Hall, Wakefield (April 15).

Woman to organize and give instruction in **Horticultural and Agricultural Subjects of Domestic Economy**—The Clerk of the Cambridgeshire County Council, Shire Hall, Cambridge (April 15).

Experimental Assistants (female) at the Ministry of Supply—The Secretary (S.E.3b), Ministry of Supply, Adelphi, W.C.2 (quoting Appts. 024/SE.3b) (April 16).

Workshop Instructor and Lecturer in Production Engineering at the Kenrick Technical College—The Director of Education, Education Offices, Highfields, West Bromwich (April 19).

Organizer for Schools Service (female)—The Director, Museum and Art Gallery, Leicester (April 20).

Assistant Livestock Expert for Animal Husbandry Work in Bengal—The High Commissioner for India, General Department, India House, Aldwych, W.C.2 (quoting Appointment 9/2A) (April 27).

Lecturer (Grade III) in the Department of Zoology—The Acting Secretary of University Court, University, Glasgow (April 30).

Lecturer (Grade IIb) in the Department of Applied Physics—The Acting Secretary of University Court, University, Glasgow (April 30).

Principal of the Ceylon University College—The Director of Recruitment (Colonial Service), Colonial Office, 29 Queen Anne's Gate, S.W.1 (April 30).

Assistant Mechanical Engineer for the Tanganyika Government Railway—The Crown Agents for the Colonies, 4 Millbank, S.W.1 (quoting M/9193).

Executive Engineer for the Public Works Department, Government of Trinidad—The Crown Agents for the Colonies, 4 Millbank, S.W.1 (quoting M/9197).

CO-OPERATION IN COLONIAL ADVANCEMENT

UNQUESTIONABLY the most striking fact to emerge from Lord Hailey's "African Survey" is the vastness of the field for scientific research and the application of its results to the needs of the native populations which are afforded by that continent. On a careful examination of the evidence which has been brought together of Lord Hailey's work of impartial observation, it is patent that if these peoples are to benefit to the full from the increased interest in their lot now manifested by the European Powers responsible for their future, a more carefully considered and scientifically informed approach to the problems of the administration of their affairs and of their future development is demanded. Nor is this an affair merely of the moment or the immediate future. No measures for the promotion of native advancement, however well-intentioned, will prove beneficial in the long run—as experience has shown time and again—which has not been framed in the light of the fullest knowledge of the essential character of native culture and its reactions to impact from outside.

As Lord Hailey has shown in detail, there is a considerable difference in outlook, in purpose and in method as between the administrative services of the various European powers concerned with African peoples. While it is doubtful whether it would be practicable, or even advisable in view of the wide differences in temperament, culture and attainment of the various African peoples, to attempt to secure absolute uniformity in administrative methods, yet unquestionably some agreement as to the general direction of policy in native development is more than desirable. In fact, sooner or later it may become an essential condition of European participation in the promotion of African development.

In these circumstances, it is a reassurance for the future that Allied co-operation is to be as effective in the colonial field as in other spheres of the joint interests of France and Great Britain. As a result of Mr. Malcolm MacDonald's recent conference in Paris, the more or less tentative approaches of the French and British colonial administrations in recent years are to be reinforced by the creation of an organization which will secure a permanent liaison between London and Paris. In the French and British Colonies themselves, which in many parts of the world, but more especially in Africa, lie adjacent to one another, there will be conferences from time to time between the governors of the British and French territories, while contact will be established between the administrative and specialist officers of the respective services.

How far this co-operation between French and British colonial authorities will lead ultimately towards any close community in fundamental principles of administrative policy it is of course at present impossible to say. On a superficial view, in outward form French colonial administrative methods, by the employment of native local chiefs and headmen, bear a certain resemblance to the methods of British 'indirect rule'; but there is at present a fundamental difference in attitude towards native authority as an instrument of administration. This would militate against anything in the nature of a condominium such as exists in the New Hebrides, which has been put forward by some as a desirable or possible outcome of the present approach to joint and common action in the Colonies between France and Britain.

British native administrative policy, fortified by experience in many parts of Africa, is wedded to the principle of 'indirect rule'; but it has not been thereby immune from criticism. On one hand, opinion among the more advanced and highly educated natives, especially in West Africa, is prone to regard its respect for native institutions and the desire to preserve their influence unimpaired as an attempt on the part of administrator and anthropologist to retard native development; on the other hand, the impartial judgment of qualified European observers fears an indiscriminate application of the principle in circumstances in which its cardinal factor, the native institution, is no longer operative, as for example in urbanized or industrialized populations, which have become cosmopolitan, in an African sense, rather than tribal. In the train of thought to which this gives rise, it is probably wise to give full weight to arguments which tend to emphasize the fact that 'indirect rule' in effect is 'local government' and stress its educative value.

At the same time, it should not be overlooked that in the light of the modern methods of investigation of social anthropology, the application of indirect rule has at times failed in scientific appreciation of the facts of native institutional practice upon which *ex hypothesi* it should be founded.

There is a larger and more far-reaching consideration to which attention may be directed. While indirect rule has as its immediate aim the preservation of tribal authority and the conservation of the forces which make for tribal integration, it does this as a means to an end—or so at least it is held by enlightened opinion—the ultimate advancement of the native peoples of Africa to take such a place among the peoples of the world as their capacities, circumstances and opportunities admit. However far they may have to go, some conception of direction, and the agencies by which this end is to be attained, should form a part of that planning on a world-wide basis which must in the long run be a consequence of the present struggle.

It is open to question, however, whether the colonial authorities, both at home and in the field, are not prone to overlook this consideration, and in danger of regarding indirect rule as to be pursued as an end in itself. Even the staunchest upholders of the principle appear to be somewhat vague as to ultimate aims. That the interests of the native population should be paramount, excellent as it may be as a principle of government, depends in its application too much upon the interpretation of 'interests' to afford any precise guidance.

In the recently issued White Paper on colonial development, while generous financial assistance is promised for both development and research, stress is laid on the primary purpose of assisting the colonies towards becoming self-supporting. Now Africa, as a whole and on the whole, is poor country, and in any event the burden of development for long must fall upon white shoulders. In the course of that development, involving presumably a change-over from what is now a bare subsistence basis for the native population to something in the nature of an industrial or potentially commercialized form of production, concern for native 'interests' may be in danger of suffering a sensible diminution.

The issues involved in the relations of a white and a native African population have been set out, though in a widely different context from that in which indirect rule has been applied, with admirable lucidity and an absence of bias by Prof. R. F. A. Hoernlé in his Phelps-Stokes Lectures for 1939*. He discusses there the native problem as it now presents itself in the Union of South Africa. As in other of the older colonies of Great Britain in Africa, the relations of white and black in South Africa up to a point have reflected the growth of a sense of responsibility in the mother country, whether due to the humanitarianism which abolished slavery or the consciousness of the 'white man's burden,' by which, in the eyes of many, imperialistic expansion found its justification. It has its modern counterpart in the 'trusteeship' which is now the avowed principle of the mandatory and colonial administration. In South Africa, however, the 'liberal spirit' which once fostered native advancement has given way, under stress of racial feeling, which is closely bound up with questions of economic competition, to a reaction which approaches native policy primarily and to all intents and purposes solely from the point of view of the maintenance of the dominance of the white and superior race in the Union. When it is remembered that here the black population outnumbers the white in the ratio of between three and four to one, the difficulties which confront those who advocate a more liberal approach to the problem become easily understood.

---

* South African Native Policy and the Liberal Spirit: being the Phelps-Stokes Lectures delivered before the University of Cape Town, May 1939. By R. F. Alfred Hoernlé. Pp. xiv+190. (Lovedale, C. P.: The Lovedale Press, 1939.) 5*s*.

It is a far cry from the complexity of social and racial conditions in South Africa to the relatively simpler societies to which indirect rule has been applied. Yet the germs of South Africa's problem are there; and they will grow unless measures be taken in time. It has been said that we are waging a war in which the aim of the Allies is to establish Christian civilization as against the paganism of nationalism and the worship of the State. But as Sir Francis Younghusband has pointed out, neither Islam nor Hinduism, nor Confucianism nor other creeds can be excluded from our aims, insomuch as we welcome their assistance. Our battle is for the principles which lie at the root of Christianity, it is true, but are no less the articles of faith of all men of good will irrespective of creed—the dignity and integrity of the individual man free to develop mind and body to the limits of his capacity within free institutions. For better or for worse, white civilization has impinged upon the black. It is incumbent upon us, if we are to be really true to the principles for which we stand in the present struggle, to see to it that our rule over the less advanced peoples is a tutelage which does not overlook their claims to co-operate in a world order in the coming era of, we hope, a more rational, as well as a more humanitarian, world.

ANGLO-FRENCH CO-OPERATION IN SCHOOLS

On September 3, Lord De La Warr, who was then president of the Board of Education, visited Paris to discuss with the French Minister of Education, M. Sarraut, the contribution which the schools of the two countries can make towards Anglo-French solidarity.

The event followed a discussion in London at the end of January last on intellectual co-operation between visiting French Ministers and their opposite numbers. Committees were afterwards set up by the Education Ministries of both countries, the aim of which is to develop existing means and to devise fresh ones for increasing among the school children of each country knowledge and appreciation of the life and culture of the other country. During the visit, which was marked by a broadcast in French by M. Sarraut and Lord De La Warr, members of the two committees met to discuss each other's work. After the visit to London to which we have already referred, a special commission of experts was set up in France to recommend ways of ensuring that French children obtain a thorough knowledge of Britain and the British, the affinities and differences of the two peoples, and their common aims in civilization. Any report which the commission has now prepared would doubtless be discussed during the Paris visit.

This move towards closer intellectual co-operation would have been desirable even had there been no war. In the present circumstances, it is inevitable and essential as a part of plans for Allied co-operation which grow more and more comprehensive. The Anglo-French declaration of war and peace policy carries with it the necessity of closer contacts between the youth and intellectual life of the two countries. Upon those who are young now will rest the responsibility of clinching victory and securing the maintenance of peace in the future. That responsibility must obviously entail closer understanding in the realm of ideas. It is in the schools, as Lord De La Warr pointed out in his broadcast, that the two peoples. so different in many ways, can learn of one another. It is in the schools that they may learn what they have both given, and are giving, to civilization and culture, what are the things for which, and against which, the present war is being waged. There was grim warning in Lord De La Warr's statement that, from the point of view of the future, the most terrible crime of the Nazi régime is the deliberate perversion of the minds and souls of their young people.

In France, where educational machinery is more centralized than in Britain, rapid innovations are possible. In English schools, nevertheless, special means have already been devised towards the ends in view. More than half a million are learning French, and the number can be increased by new effort. New programmes have been drawn up for school broadcasts and new plans for a wide circulation of films and for special lecturers to tour the schools. There are possibilities, too, of new books on French life, and of arranging exchange visits of teachers and children. These activities should make a substantial contribution to the preservation and development of the ideals for which Britain and France stand.

THE ULTRACENTRIFUGE

The Ultracentrifuge

By The Svedberg and Kai O. Pedersen, in co-operation with J. H. Bauer and E. P. Pickels; G. Boestad; E. O. Kraemer and J. B. Nichols; O. Lamm; A. S. McFarlane; R. Signer. (International Series of Monographs on Physics.) Pp. x+ 478+ 31 plates. (Oxford: Clarendon Press; London: Oxford University Press, 1940.) 40*s*. net.

PROF. SVEDBERG'S institute at Uppsala has been for some years now a world-famous international club, with notices in several languages which may or may not include Swedish. The book just published summarizes the work of the staff and visitors with the ultracentrifuges during fifteen years of steady progress. It is significant of its international character that the authors consist of three Swedes, one Dane, four Americans, one Scotsman, and a Swiss. Of the two chief authors, Prof. Svedberg confines himself mainly to the constructional part, showing clearly how, "given the height and thickness of the column of solution and its distance from the centre of rotation, all other mechanical characteristics of the ultracentrifuge can be directly derived". The other main author, Dr. Pedersen, expounds, with the same unflagging patience with which he helped to develop, all the minute points of detail which must be observed before the apparently simple results can be obtained. The section on results, also largely by Dr. Pedersen, is fairly short, which is right, since these are all in the literature and a full bibliography is given, whereas much of the technical part is published here for the first time. The greatest interest of all, perhaps, is contained in the section on rotor design, where the succession of hopes, disappointments, and triumphs reads like a novel. Visitors have always heard of mysterious conferences with a "steam turbine expert from Stockholm" when a new rotor was in contemplation. The mystery man now seems to be revealed as G. Boestad. One wonders whether he is the artist responsible for the quite unearthly beauty of the modern rotor (see Fig. 97).

The book as a whole has both the advantages and drawbacks of a composite work. Every detail is written by someone who knows all about it, but despite the strongly unifying personality of Svedberg, it is not one of those books in which every word follows inevitably on its predecessor. There is too much repetition, due partly to the otherwise attractive method of covering the ground first in outline and then in detail, partly to imperfections in the scheme of classification or to different interpretations of it by different authors. But in spite of this, and of the fact that it is a standard work of reference, the book is quite surprisingly easy to read. As a work of reference it might profitably have incorporated some of the invaluable hints contained in a typed document known as "Watson's Manual", such as what to do when the rotor temperature soars skyward, or the oil pressure suddenly vanishes. A more serious omission is the account of results obtained with air-driven ultracentrifuges, but as explained in the preface they have been included in the bibliography.

It is interesting to speculate on the future of the ultracentrifuge. So far as resolving power goes, not much more can be expected, even if refinements such as synchronized light-source, oval cell-holes, etc., are introduced. The power-consumption has been greatly diminished recently, but it now seems scarcely worth pushing it much lower. The capital cost remains, as always, high, being due more to the large number of accessories than to any single item. The ease of operation, including measuring the results, is now as good as could be desired if one is content to guess the base-line instead of measuring it; but it would be a great convenience if some means could be found for obtaining the true base-line without an extra run and for automatically subtracting it. On the whole, therefore, no sensational technical developments are to be expected. What about applications? It can be safely predicted that whenever a new protein is isolated (or is thought to have been isolated) it will be sent as now to an ultracentrifuge centre for study of its homogeneity, sedimentation constant, molecular weight, and possibly *p*H-stability curve.

It is possible that purely ultracentrifuge researches will give place almost entirely to this monotonous but highly necessary work as the rate of isolation of new proteins increases and the general laws of protein aggregation cease to have any more surprises; but the ultracentrifuge will also continue to be of importance as an adjunct in other research, for example, in any experiments on the action of reagents on proteins or in the study of pathological sera, plastics, etc., which are highly complicated subjects still in their infancy. If I dare predict a negative, it is that the preparative separation of the lower molecular proteins by ultracentrifuging will never be a useful method, although the apparatus for it already exists. The separation of high-molecular substances like the viruses is another question, and here the method has thoroughly established its usefulness.

Finally, a word on the still controversial question of air-drive versus oil-drive. Svedberg originally chose the latter on grounds of efficiency, and the figures quoted in his book amply justify the choice; but the question of drive has become coupled with three other questions, namely horizontal or vertical axis of rotation, material of rotor, and hydrogen or high vacuum as surrounding medium. For optical measurements the horizontal axis is better, while for preparative purposes the vertical one is essential. The two rotor materials are steel and duralumin. Steel gives slightly higher resolving power at the cost of a large increase in strength of casing and foundations, in power required to accelerate and in thickness of bearing and therefore power required to drive. Since the air-drive is too inefficient to be used satisfactorily with steel, the exponents of it have had to develop the possibilities of duralumin, but have reaped the latter's own advantages in compensation. One of these, the small bearing shaft, has made it practicable to run in high vacuum instead of hydrogen; and apparently if the vacuum is good enough it is definitely superior to hydrogen. Thus in every way except resolving power and possibly length of life, duralumin is superior to steel; but for low-molecular proteins resolving power is of cardinal importance, so that until some new material is produced, steel will continue to be used where the appreciable difference in capital cost can be afforded.

J. St. L. Philpot.

FUN AND PHYSICS

Mr. Tompkins in Wonderland

Or Stories of *c*, *G*, and *h*. By Prof. G. Gamow. Pp. x+92. (Cambridge: At the University Press, 1939.) 7*s*. 6*d*. net.

Mr. TOMPKINS was a bank clerk seeking distraction at the end of a heavy day. Bored almost to tears by the inevitable Hollywood stuff at the 'movies', and attracted by the title "Space, Time and Cosmology" which he thought might offer something in the Jules Verne vein, he drifted into one of a series of lectures at the local university on topics in modern physics, and that was where his troubles began. He did not understand the lecture. In fact he was not able to follow it sufficiently well even to misunderstand it, and retired to bed in that state of mental depression which is not an unusual after-effect of attendance at lectures on mathematical physics. His rash experiment, however, gave rise to the series of dreams, one might almost say nightmares, retailed in the first half of the book. The second half contains the lectures out of which the troubles arose.

In his dreams Mr. Tompkins finds himself in a succession of universes in which the fundamental natural constants—which in our universe are, fortunately, either so immensely large or so extremely minute that only mathematical physicists need to worry about them—have assumed values which bring their more remarkable consequences under direct observation. In some, that natural "speed limit", the velocity of light, is reduced to ten miles per hour; moving objects become unbelievably flattened; watches gain or lose in a most puzzling way, and a host of other "relativity effects" disturb the equilibrium of the unhappy little bank clerk. In others the "quantum-constant" swells to 1 erg sec. (surely not 1 erg/sec. as is stated in the text) and produces curious consequences in a game of billiards. In yet another the "uncertainty factor" assumes finite proportions, and a frightened gazelle dashing through a grove of bamboos emerges as a diffraction pattern. For details of Mr. Tompkins's adventures in these strange worlds the reader must consult the text.

In a world where popular expositions of the ideas of modern physics have been almost as plentiful as blackberries, Prof. Gamow has hit on something quite novel; and—incidentally—has by his dedication forestalled all possible criticism, for what reviewer could have the heart to comment adversely on a book dedicated jointly to Lewis Carroll and Niels Bohr? If Mr. Tompkins's adventures are not quite as amusing as those of the immortal "Alice", nor his "Wonderland" anything like so convincing as hers, that is because the author's purpose is didactic, and his imagination fettered by his equations. Truth, as portrayed in modern physics, is distinctly stranger than fiction, and the 'wavicle' can never hope to rival the grim reality of the Jabberwock. It would be difficult to imagine any better way of gaining a glimpse of the strange world in which the mathematical physicist lives, during business hours, than by accompanying Mr. Tompkins in his adventures.

The "dreams" collected in this volume first appeared in the pages of *Discovery*, and it is interesting to note how, even during the course of their publication, the outlook of modern physics changed. We do not know whether Mr. Tompkins was disappointed, or relieved, to be informed by the professor towards the end of the book that the closed pulsating universe in which, in his first adventure, he so narrowly escaped an extremely "stuffy death" was but a nightmare after all, and was no longer regarded as having any physical reality. However, as by this time Mr. Tompkins was busily engaged in courting the professor's daughter, he had possibly ceased to be interested.

The illustrations which enliven the pages of the text have a somewhat smudgy appearance, as if they were suffering from a rather large "wave of indeterminacy". Perhaps this is intentional, but the effect is not attractive. Prof. Gamow's stories fully deserve preservation in book form. Mr. Tompkins, now safely married, no longer needs the dubious excitement of university lectures. Should, however, his father-in-law's expositions, now, no doubt, transferred to the domestic circle, induce still further adventures, we hope Prof. Gamow will be at hand to report them.

J. A. CROWTHER.

CHEMICAL APPLICATIONS OF SPECTROSCOPY

Chemical Spectroscopy
By Prof. Wallace R. Brode. Pp. xi + 494. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1939.) 36*s*. net.

IT is unquestionable that this book will have a wide appeal. Everyone engaged in spectroscopy, no matter what branch, will find something of interest and perhaps some useful advice and suggestions within its covers; everyone interested to know 'the how, the why, and the wherefore' of spectroscopy will find an answer to the majority of his queries. Some idea of its scope will be gathered from the chapter headings: introduction; atomic and molecular spectra; emission spectra (apparatus); qualitative analysis, spectrum tables, and standard samples; quantitative analysis; resonance and chemical structure; absorption spectra; absorption spectra (apparatus and methods); application of absorption spectra data; infra-red and Raman spectra; theory and description of colour; laboratory experiments; theory and practice of photography; equipment and arrangement of a spectrographic laboratory. In these chapters are laid down the fundamental theory and practice of spectroscopy, interspersed with valuable information on technique, on recording of spectroscopic data, on teaching spectroscopy, and on the sources from which spectroscopic apparatus and materials are procurable.

But these topics occupy only 313 pages. What of the rest of the book? It is given over to three things. First, a bibliography of books on emission and absorption spectra, followed by a list of 123 references to the most important original publications. Then come 120 pages (pp. 327–446) of spectral data arranged in tabular form. These tables, all that a student will require, give persistent lines by wave-length from 1850 A. to 7950 A.; the persistent lines of elements (in alphabetical order); the principal lines by wave-length from 2000 A. to 7998 A.; the principal lines of seventy-two elements (in alphabetical order), with ionization states, intensities of arc and spark spectral lines, wave-lengths of control lines and of lines from other elements, the presence of which in a sample would give interference and probably vitiate results; spark spectrum of air; principal lines of discharge spectra of ten elements (alphabetized); Fraunhofer lines in the sun's spectrum; various conversion tables. Finally, there are thirty-five full-page charts which appeal because of their usefulness—and their novelty. They show the iron spectrum from 2310 A. to 5090 A., and on them are marked identified iron lines and the indicated positions of the principal lines of other elements. These charts are "intended for use as a projection screen or for the superposition of an enlarged strip of the unknown spectrum and adjacent iron comparison spectrum". We must congratulate Prof. Brode on these tables and charts and pay admiring tribute to the industry and patience which their compilation has required.

The book contains a very large number of diagrams and photographs. Whilst, generally, these are very good, there are certain criticisms which must be made. The diagrams are characterized by a neatness and compactness which quite frequently results in the reproduction of diagrams on such a reduced scale as to make them rather difficult to examine, particularly as lettering is sometimes so small as to necessitate re-focusing the page for comfortable reading (for example, Figs. 4.4 (p. 68), 8.19 (p. 165), 9.11 (p. 208), 12.33 (p. 272)). Many photographs of apparatus are not too well reproduced, they are slightly fuzzy, and it is questionable if photographs of apparatus without diagrams of the optical system (there are several) will mean very much to a beginner. Some of the spectrograms lose clearness and definition by being reproduced on such a small scale (for example, Figs. 3.30 (p. 54), 4.6 (p. 71), 12.8 (p. 246)).

This book is essentially a practical book, and those who go to it for treatment of the theory of spectra will find it disappointing. The author has limited his discussion of theory to very concise statements on fundamental points. Particularly is this so with respect to his treatment of infra-red and Raman spectra. Whilst there is no doubt that these spectra constitute a field of their own, it is to be regretted that, since the author has elected to include them, he did not extend this chapter so as to give more detailed information on the specialized technique required for their study, concluding with a short account of the scope and utility of each when used separately and when the data from both are correlated. A detailed discussion would not have been necessary, and yet the undoubted success of these methods in the elucidation of molecular structure constitutes an important branch of chemical spectroscopy. But perhaps, on the whole, it might have been preferable to have omitted their discussion altogether.

Chapter xii, which deals with laboratory experiments, merits special attention. The exercises commence with the calibration of a spectrograph and then go on to the qualitative and quantitative determination of elements, the measurement of visible and ultra-violet absorption spectra, and the use of the photronic cell. The exercises, perfectly straightforward in themselves, are described in a most complete, careful, and attractive way, and will prove extremely useful as a basis for an elementary experimental course in chemical spectroscopy. The only criticism which may be made is that these exercises can, however, only be carried out when there is available in the laboratory a considerable quantity and range of spectroscopic apparatus.

No book of this size and importance can be expected to be entirely free of errors or devoid of sections or features to which some measure of adverse criticism can be applied. This book is no exception. But the feeling left in the mind of the reviewer after perusing it is that the book, although rather expensive, is a welcome and timely addition to the literature of the subject and can be thoroughly recommended.

W. ROGIE ANGUS.

HUMAN EMBRYOLOGY

The Essentials of Human Embryology
By Prof. Gideon S. Dodds. Second edition. Pp. ix+316. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1938.) 20*s.* net.

AS was to be expected in a work on human rather than comparative embryology, the second edition of Prof. Dodds's text-book, which is intended mainly for medical students, does not differ greatly from the first, published nine years earlier. Many of the chapters are little if at all altered, but there are certain sections in which changes have been introduced as a result of recent researches. These relate more particularly to the early stages of development, the testis and ovary, the placenta, the ages of embryos, the formation of bone, the pharynx and its derivatives, the blood vessels, and the growth of nerve fibres. Moreover, the chapter on ovulation, menstruation, and pregnancy has been almost entirely rewritten.

In the fourth chapter there is an interesting account of the four very young ova known as the Miller, Bryce-Teacher, Peters and Spee ova. The section on the determination of the age of embryos includes useful tables illustrating the growth, and one of these, which is supplied by Dr. Streeter and hitherto unpublished, includes ages below eight weeks, the figures being based upon young human embryos compared with accurately timed monkey embryos. It is to be noted that in the chapter on the nervous system there is included a brief account of Speidel's recent research on the growth of nerve fibres in the web of the tail of the tadpole.

The chapter on ovulation and the related processes deals with certain matters which are not beyond dispute, and the statements made are not always quite accurate. Thus, in the formation of the corpus luteum, the follicular cavity is partly filled in by the ingrowth of connective tissue and vessels from the wall and not simply by the hypertrophy of the epithelial cells, as here described. Further, the hæmorrhage which takes place before œstrus in the bitch cannot correspond to the inter-menstrual bleeding of women occurring at about the time of ovulation, since the latter process in the dog does not supervene until œstrus, and it is well known, as pointed out by Heape, that the bitch will not usually receive the male until external bleeding is quite or nealry over.

Such defects as those indicated, however, must not be held to detract from the general usefulness of the book. F. H. A. MARSHALL.

A SKELETON HISTORY OF SCIENCE

Science since 1500
A Short History of Mathematics, Physics, Chemistry, Biology. By H. F. Pledge. Pp. 357 + 15 plates. (London: H.M. Stationery Office, 1939.) 7*s*. 6*d*. net.

THIS book gives a very compact summary of the history of the chief sciences during the period indicated in the title, and also some retrospects covering earlier periods. The mode of presentation varies. Some of the chapters follow the main divisions of science, others confine themselves to some special problem, while others again are rather mixed bags the contents of which are strung together on somewhat slender threads.

The attempt to crowd so much into a single volume inevitably involves large gaps. The principal weakness of the book lies, however, in its inclusion of too much, rather than of too little, in the allotted space. The actual text consists of little more than 300 pages, and there is an index of 27 double-column pages listing some 3,000 names and subjects. In the circumstances, we have something like a skeleton rather than a living body. The various catalogues and handbooks published by the Science Museum are all of them more or less helpful. The present volume is probably the most ambitious, and probably one of the least helpful, of them all. The claim that the book is suitable for the general reader, for the beginner, etc., cannot be seriously sustained. If this was really one of the author's aims, then he should have reduced the number of facts dealt with, and thereby made room for more adequate explanations, so as to make the dry bones live. Additional space for expository purposes could also have been gained by omitting most of the illustrations, which are more curious than important, and some irrelevant matter.

It seems odd that Mr. Pledge, who makes quite severe demands on the reader's previous knowledge of science, should have refrained from assuming an elementary knowledge of European geography, and considered it necessary to devote 12 pages to maps and tables showing the birthplaces of men of science. I have not checked their accuracy, but one error attracted my attention because it is repeated in the main text. Mr. Pledge asserts twice that Spinoza was not born in Holland (pp. 51f.). But he was; namely, in Amsterdam. Again, Mr. Pledge sacrifices two pages to a facsimile and translation of a passage from a thirteenth-century Hebrew manuscript in which motion is described as a cause of heat. To judge from the section in which the facsimile is inserted, it appears to be regarded by Mr. Pledge as an anticipation of the kinetic theory of heat. Actually, the passage is irrelevant, as it has no bearing on the question of *molecular* motion, nor on the question whether heat is a kind of substance or a kind of energy. Incidentally, it may be pointed out that the facsimile is printed upside down!

Mr. Pledge does occasionally depart from the narrow path of bare summary. But his remarks, in those cases, strike one as tendentious and misleading, or at least as very questionable. For example, in a chapter on early mathematics, the notion of infinity is dealt with in a manner which betrays a curious mixture of ideas pertaining to mathematics, sociology, and theology, and the net result is summed up in the following delectable statement: "For the step-by-step communion with the infinite by a series of sacraments, science has substituted the step-by-step communion with it by a series of hypotheses and experiments. But the infinity remains." What has this to do with the mathematical conception of infinity? Again, here is Mr. Pledge's amusing incursion into comparative psychology: "the domestic dog appears to believe that he can impart motion to his master infectively by fervent imitation of the actions of going for a run"! Mr. Pledge's adventures into the realm of philosophy are on the same level of infelicity. The terms "philosophy" and "philosophical", etc., are used in such varied and nebulous senses that one is made to wonder what he really means by them; and, even apart from this vagueness, his quasi-Comtean remarks about the relation between philosophy and science are made in defiance of the fact that eminent thinkers like Descartes, Leibniz and Kant were men of science as well as philosophers, and that the same sort of combination is found among such contemporaries as Whitehead, Russell and Eddington.

Finally, reference may perhaps be made to another kind of crudity which rather mars the book, namely, the use of such phrases as "the Jew, L. Kronecker", the "Jew convert" Cantor, etc. Mr. Pledge most probably does not mean to be unfriendly, but the use of such expressions reminds one of a significant remark made, more than a hundred years ago, by a journalist of distinction. Some people, he protested, hate the Jews merely because they are Jews, some tolerate them in spite of their being Jews, and some even like them just because they are Jews; but nobody ever seems to forget that they are Jews! A. Wolf.

VISCOSITY AND MOLECULAR STRUCTURE

By Dr. H. Mark and R. Simha

THE development of the molecular theory of matter has as a consequence that an increasing number of empirical constants, by which one characterizes the behaviour of a macroscopic sample, are brought into quantitative relation with the molecular structure of the material. For example, it has long been known that the *index of refraction* can be connected with the *mobility of the electric charges* in a given substance, and therefore can be used to determine the electrical polarizability of the molecules in a quantitative way. Similarly, the *dielectric constant* can be used to get quantitative information on the *distribution of the electric charges* in the molecules of a given substance, and it was P. Debye, especially, who succeeded, together with a number of collaborators, in establishing a quantitative theory which combines the macroscopic empirical constant with the molecular properties.

Recently, it seems that another quantity, which has been used for some time to characterize a given system from an empirical point of view, must be understood and evaluated from the angle of the molecular theory of matter. This is the *internal friction* or *viscosity* of solutions. This property has been accounted for in ideal gases by the kinetic theory of gases, by consideration of the masses and velocities of the individual molecules and their irregular collisions. But our knowledge of the viscosity of condensed systems had not progressed so far, although it was obvious that much valuable information would be obtained if viscosity could be interpreted kinetically.

During recent years, some special developments have been particularly favourable to the solution of this problem. The most important of them are : (1) the development of a quantitative theory of liquids ; (2) the accumulation of a large amount of experimental data on high polymeric substances and their solutions, and the development of the ultracentrifuge, which enabled us to get independent information on high molecular compounds.

This progress encouraged the attempt to trace the viscosity of solutions, and especially of solutions containing high molecular substances, back to the fundamental properties of their elementary particles, namely, to the size and shape of the molecules and to their power to fix a certain amount of solvent on themselves. Such attempts were started about fifteen years ago from different points of view. An increasing number of scientific investigators have turned to the subject since then, and we are now obtaining a first insight into the connexion between the viscosity of a solution and the fundamental properties of the dissolved material. It is not suggested that any finality has been reached in this field, but it seems that experimental conditions which are necessary to get trustworthy information have been worked out, and that the results which can be presented to-day are consistent among themselves and agree with the findings by other experimental methods.

It may therefore be appropriate to enumerate briefly the different essential steps which have led to this kinetic elucidation of viscosity and to present a few results which may be presumed to have reached a certain degree of reliability. It may be that in the future such results will have considerable interest in biochemistry, physiology and chemical industry.

Early Fundamental Investigations

Einstein[10] was the first to derive with incomparable clarity an equation showing how spherical particles which are dispersed in a liquid would raise its viscosity. He found, so early as 1905, that the increase of internal friction is proportional to the total amount of dissolved volume, but surprisingly independent of the degree of dispersion. A few large spheres produce the same viscosity increase as many small ones, provided their total volume remains constant. A few years later, Bancelin[1] and Sven Odén[36] confirmed experimentally Einstein's theoretical results.

Having received experimental confirmation, the Einstein equation could be used to determine the total volume of the dissolved phase, that is, the degree of swelling or solvation which the material undergoes during solution. For example, it was found that a molecule of cane sugar carries with it about five or six molecules of water tightly fixed upon its surface during the diffusion in the liquid.

But the combined theoretical and experimental results seemed to block any possibility of getting information concerning the size of the dissolved particles, because it was found that the viscosity should be independent of this quantity.

However, during the following years an increasing number of empirical facts showed that there evidently was some relation between particle size and viscosity in quite a number of cases. Measurements of Biltz[3], Berl and Buttler[2], Hatschek[21], Duclaux and Wollmann[9], Ostwald[30], and Staudinger[35] gave indications that the viscosity of very dilute solutions of many typical high molecular substances decreases if one degrades the original material, and that it is increased if one raises the molecular weight. As this is apparently in disagreement with the Einstein equation, it was concluded that these substances do not behave as spherical particles.

From here on a double development became necessary: (*a*) to accumulate more reliable and quantitative empirical data in order to have a sound experimental background; and (*b*) to derive theoretical equations for non-spherical particles.

THE PROBLEM OF NON-SPHERICAL PARTICLES

Much successful work was contributed in both directions. It was especially Staudinger and his collaborators who extended viscosity measurements considerably, investigating systematically the influence of molecular weight, concentration, temperature, and solvent; and they established an empirical rule, the well-known viscosity equation of Staudinger[35].

This equation states that the viscosity increase due to the dissolved substance is proportional to its molecular weight, provided that the solution is sufficiently diluted. Very careful viscosity measurements by Meyer and v. d. Wijk[29], and by Kraemer and Lansing[25] showed, however, that this relation is not exact but is subject to certain deviations. But it can be safely regarded as being a valuable rule for the estimation of molecular weight, and it has proved to be very fruitful for further progress in this field.

While this experimental material was accumulating, a series of successful attempts to develop equations for non-spherical particles was made. Jeffery[23] was the first to start this development. He was followed by Eisenschitz[13], Boeder[5], Haller[20] and Kuhn[27]. These investigators developed equations making it possible to calculate the viscosity increase due to longish particles, as the Einstein equation did for spherical particles. Obviously these relations were expected to explain theoretically the Staudinger equation, but at first sight there seemed to be a lack of agreement.

The Staudinger equation states that the viscosity increase is proportional to the molecular weight, while hydrodynamics indicate that it is proportional to the square of the molecular weight. Guth and Mark[18] proposed qualitatively an explanation for this discrepancy, but Kuhn[27] was the first to work out a complete and consistent theory.

If one assumes that the dissolved particles are *not stiff rods but flexible threads*, the experimental findings and the theoretical equations harmonize in a manner which shows that the idea of long flexible chains rolled or wound up to a more or less cluster-like unit is the right way out of the dilemma.

DEVELOPMENT OF THE HYDRODYNAMICAL METHOD

To get a final check on the value of this explanation, further experimental and theoretical work was undertaken. Eirich, Bunzl and Margaretha[12] studied systematically the behaviour of model suspensions with particles of exactly known size and shape. Glass, silk, rayon, mushroom spores, bacteria, microscopic crystals, etc., were used; the size varied from 1μ to 100μ diameter, the shape from spherical particles to rods with an axis-ratio of about 50. The viscosity of proteins was carefully investigated by Fahry and Green[14] and by Polson[32]; the latter giving an extensive comparison of the data obtained by viscosity measurements with the results of the Svedberg ultracentrifuge. At the same time Houwink and Klaassens[24], Kraemer and Lansing[25], Bogue[6], Kratky and Saito[26], and others contributed valuable experimental material on different high polymeric substances.

The hydrodynamical treatment was pushed forward by Guth[17,19], Huggins[22], Kuhn[27], and Simha[34], in the direction of both spherical and non-spherical suspensions, taking into account the influence of higher concentration and of the Brownian movement.

Another group of recent articles represents comprehensive work aiming at the comparison of all available data and their survey from a common point of view. Sakurada[33], and particularly Bredee and de Booys[7], and Huggins[22], have contributed in this direction.

CONCLUSIONS

As the result of the experimental and theoretical work briefly described above, some data contained in the following tables can be usefully considered. They show that although we still have to consider that we are in an early stage of the complete molecular interpretation of viscosity, a number of very interesting molecular constants can be derived from such measurements.

Table 1 shows the size and shape of some protein molecules as determined by viscosity measurements, and at the same time the corresponding values obtained with the Svedberg ultracentrifuge.

TABLE I. SIZE AND SHAPE OF PROTEIN MOLECULES IN AQUEOUS SOLUTION*

Substance	Molecular weight		Axis ratio	
	from viscosity	from ultra-centrifuge	from viscosity	from ultra-centrifuge
Ovalbumin	41,800	42,000	8·5	3·8
Hæmoglobin	70,300	68,000	5·9	3·8
Serum albumin	71,800	70,000	9·8	4·9
Homarus hæmoglobin	793,000	800,000	—	—
Tobacco mosaic virus	$17{\cdot}43\times10^{6}$	—	36·9	—

* Compare refs. 4, 7, 14, 16, 28, 32.

TABLE 2. MOLECULAR WEIGHT, SOLVATION AND SHAPE OF SOME CELLULOSE DERIVATIVES*

Substance	Molecular weight	Volume of the solvated particle as multiple of the dry volume	Deviation from the spherical shape†
Nitrocellulose	500,000	345	2·5
,,	150,000	121	3·7
,,	40,000	40	2·6
Cellulose acetate	50,000	97·5	3·0
,, ,,	14,000	31·3	3·2
,, ,,	6,400	13·2	2·1

* Compare refs. 2, 7, 8, 9, 15, 35.
† Spherical shape is characterized by the value zero.

It can be seen that, as regards the size of the particles (molecular weight), the two methods agree fairly closely, while viscosity gives a higher axis-ratio than the ultracentrifuge.

Table 2 contains similar information on the molecular weight, solvation, and shape of some cellulose derivatives. In this case no experimental data from the ultracentrifuge were available, and therefore an experimental check of the values is not possible. However, other methods (osmotic pressure, diffusion, etc.) confirm the above values and show that they certainly reflect to a considerable extent the true conditions in these high molecular suspensions.

TABLE 3. MOLECULAR WEIGHT, SOLVATION AND SHAPE OF SOME POLYSTYRENE SAMPLES*

Molecular weight	Volume of the solvated particle as multiple of the dry volume	Deviation from the spherical shape†
280,000	205	7·3
220,000	80·5	5·7
23,000	15·4	3·1
2,400	2·65	0·4

* Compare refs. 7, 31, 33, 35.
† Spherical shape is characterized by the value zero.

TABLE 4. SOLVATION OF DISPERSED SUBSTANCES WITH APPROXIMATELY SPHERICAL PARTICLES*

Substance	Degree of solvation (per cent)
Mushroom spores	nil
Colloidal sulphur	nil
Kresol-formaldehyde-resin	10–40
Cane sugar	50
Ovalbumin	120
Gamboge	800
Gelatine	1,000–2,000

* Compare refs. 1, 4, 6, 7, 12, 14, 24, 32, 36.

Similar data concerning some samples of polystyrene are given in Table 3. They are equally supported by the results of other experimental methods.

Tables 2 and 3 show that with increasing molecular weight the solvation of the substance investigated increases, and in the case of styrene the deviation from the spherical shape also assumes higher values.

Table 4 gives the solvation of some systems the particles of which are approximately spherical, and shows that different materials behave very differently as regards their power to absorb certain amounts of solvent and to carry them about during their molecular movements.

If account is taken of the fact that it is very difficult to get any trustworthy quantitative information on size, shape, and solvation in the region of such high molecular weights, it will certainly be admitted that viscosity measurements provide a very valuable and welcome means of obtaining quantitative information on the molecular structure of such materials.

PLANT HUNTING THROUGH THE CENTURIES*

BY F. KINGDON WARD

IN a sense, man has been searching for useful plants ever since he first appeared on the earth. Even in his hunting days before the end of the Ice Age he probably supplemented his diet with berries, seeds and roots. But for our present purpose we may ignore man before he became a cultivator, merely noting that even in those remote days he was a plant hunter.

We may perhaps picture primitive man slouching painfully across that early European landscape, haunted by the spectre of hunger, a child of sudden overwhelming impulse, fearful and bewildered, clutching, famished, at a handful of grass seeds or coloured berries, gnawing tough fruits, or chewing leaves. Through these bitter centuries he was learning gradually the first lesson man was compelled to learn in his dealings with the tremendous, infinitely old vegetable kingdom which he was destined one day to control: the difference between cellulose and starch or sugar, the difference, that is, between the structural materials of plants and the products they manufacture and set aside for future use; the cell wall and the cell contents. For cellulose is insoluble and therefore useless to man as food, since he cannot assimilate it; but sugar is soluble and starch is easily converted into sugar. Only the plant store-houses—fruits and seeds and certain usually underground parts and growing points—contain available food. The object of cultivation, besides being a matter of greater convenience, is to increase the soluble cell contents and eliminate as much as possible of the framework.

To get the botanical exploration of the world into perspective, it is necessary to go back eight or ten thousand years. The outline of the world was not then very different from what it is to-day. But there have been great changes in the mantle of vegetation since then, changes in the relative positions, and in the extent of forest, steppe and desert which are ultimately dependent on rainfall. It was vegetation, and hence climate, which determined not only which direction wandering man should take, but also where he should first begin to settle.

Although man must have been a hunter before he became a herdsman and a husbandman, through long ages all three must have existed together in different parts of the then habitable world. Man could have hunted only on the steppes; he could not have lived in the desert, and in the forest he would have been a complete vegetarian. It would therefore be misleading to divide the time period into the three ages of hunting, herding and husbandry. Broadly speaking, herding suggests a nomadic, cultivation a settled, life. But there are many villages in Tibet to-day where no crops are grown, while in many parts of the world agriculture is itself nomadic. In densely forested regions the same patch of ground can only be cultivated at long intervals, and there comes a time when the village has to move. Abandoned village sites are common, for example, in far northern Burma.

Since we are dealing with a continuous evolution, no classification of the plant exploration period on a time basis can be other than arbitrary. Nevertheless, the following rough guide may be found convenient, though it involves a good deal of overlapping.

(*a*) *The Search for Food Plants.* Prehistoric period, from the beginnings of cultivation to the invention of writing, from about 7000 B.C. to about 4000 B.C.

(*b*) *The Search for Economic Plants, other than staple foods, but including many food plants of secondary importance.* Historic period, from 4000 B.C. to the discovery of the New World in A.D. 1492.

(*c*) *The Search for Garden Plants.* Modern period from A.D. 1492 to the present day.

This corresponds to some extent with three successive steps in the evolution of civilization, namely, (i) the search for economic plants, or as it is called to-day, raw material; (ii) the large-scale cultivation in any convenient part of the world of economic plants; and (iii) the large-scale manufacture of synthetic products from simple vegetable raw material. So we take up the story of plant hunting at the end of the pre-agricultural age; the earliest plant hunters sought food plants.

Cultivation must have arisen independently in several centres; settlement was the basis of civilization. The primitive tribes of the eastern Himalayas, although new-comers (their chief crop is maize, which was unknown in Asia before the discovery of America) show traces of what early agriculture may have been. In the vicinity of Abor and other villages, fruit trees such as Artocarpus, peach, cherry, Citrus, quince, are much commoner than elsewhere, showing how settled people eat the fruits and spit out the seeds, which germinate in the village clearing.

---

* Substance of a course of lectures delivered at the Royal Institution on January 16, 23 and 30.

In the Mishmi Hills, the medicinal herb *Coptis Teeta* grows in the forest, above the highest cultivation. The natives clear the ground, cut down a few trees, and encourage the Coptis by stifling opposition. These tribes also show how from very early times man has used vegetation in its raw state, as timber, etc. The use of bamboos for water-tubs, lianas for ropes, or the fibrous bases of palm leaves for cloaks are examples. The first thing man ever made for himself was a wooden (cellulose) club. One of the latest things he has provided himself with on a vast scale is also made of cellulose—nitro-cellulose, the basis of many high explosives.

The natural distribution of plants over the earth has until recently been a decisively limiting factor in man's economy. Until the exploration of the world was far advanced, the people of Malaya had no chance of cultivating Brazilian rubber, nor the people of Brazil of cultivating Arabian coffee. Nor were these substances required in bulk. Not only are the plants of different parts of the world different, even for the same climate, but also they are of unequal value. Nowadays this unevenness of distribution can be levelled up by transporting any plant from where it grows naturally to any part of the world where it will grow. Plants regarded as of less importance are swept away to make room for huge crops of one kind, such as rubber, quinine, sugar cane or tung oil. The vegetation of the earth is everywhere being rapidly altered by man.

It has been shown by de Candolle, and more recently by Vavilov and others, and endorsed by antiquarians, that the earliest civilizations began in those regions whence most of our oldest cultivated crops have been derived. But nowadays the great centres of civilization bear no relation to, or are quite independent of, the original homes of the cultivated crops. That is a very significant fact.

After food, man's chief need was clothing. When animal skins became rarer, he turned to cellulose, and wore leaves. To-day most of the world's clothing is made of cellulose products such as cotton and rayon. The art of weaving is older than that of writing.

In the Ancient World new ideas diffused slowly, but they were quickened later as the result of pilgrimages, campaigns like that of Alexander, and trading. When civilization was disintegrating all over the world between A.D. 1050 and A.D. 1250, owing to the attacks of barbarians, cellulose came to the rescue with the increasing use of paper, which made books possible. Knowledge was preserved without accumulating error, and degenerating into legend. The earliest paper—papyrus (pith), *Aralia japonica* (pith), and palm leaf—was practically pure cellulose and useless for books. But the invention of paper which would take print was a fundamental step in the forward march of civilization. Printing itself was of less importance than paper; it increased the speed of diffusion, without any corresponding increase of accuracy, so that myths were as readily propagated as truth; for example, in modern times the widely believed story of mummy wheat germinating.

From the beginning, agriculture has had a disastrous effect on the natural cover of vegetation, and one of ever-increasing severity, especially in areas of natural grassland and in mountainous forested country where shifting cultivation is practised. The plough has proved one of the most destructive weapons ever put into the hands of man. Within the last few centuries pastoral man has become almost as destructive as agricultural man, as a result of cutting down forest to increase the area of pasture. The damage is clearly seen in many parts of the eastern Himalayas, where the local climate is being altered, and much land becoming derelict.

Two hundred years after Marco Polo's journey, the overland route through Eurasia was virtually closed. Diaz then rounded the Cape, and Columbus discovered the New World. As a result, the age of maritime exploration began, and more was learnt of tropical than of any other type of vegetation. The coasts and the estuaries of great rivers were explored. But for lack of roads, the interiors of the continents remained hidden, and it was not until the nineteenth and twentieth centuries, and the intensive search for gold, that the building of roads and railways made inland exploration possible. The historic voyages of the seventeenth and eighteenth centuries did nothing to make known the vegetation of the interiors of continents. The interior of Africa, of Australia, of Central Asia and of South America have been known to scientific men for little more than a century; the interior of Tibet, and of New Guinea, for less than fifty years. Now that transport problems have been solved, new obstacles in the form of 'national interests' are making scientific exploration over considerable portions of the least-known parts of the world increasingly difficult.

After food and fibre plants, man sought dyes, drugs, soap, scents and such-like things. While searching for food plants he may have discovered soothing or uplifting properties by chance, for example, opium poppy seeds, which the Mishmis eat, tobacco, hemp. Fermentation of his stored grain taught him the use of alcohol. In modern times, oil-producing fruits and seeds are in great demand. The plantation industry grew up with the Mechanical Revolution; raw material was needed to feed the machines. When the topography of the world had been mapped, the mapping of the vegetation and of the rocks followed. From the beginning, unusual looking plants attracted man's attention ; and it was but a short step to cultivate flowers. With the advance of civilization, horticulture took a prominent place. In spite of the intensive exploration of the world for new plants during the last 1,500 years, not one unknown economic plant of any importance has been newly discovered. Even tung oil and soya bean, than which few plants have come into greater prominence recently, were cultivated several thousand years ago. On the other hand, many beautiful garden plants have been newly discovered.

Apart from horticulture, perhaps five hundred species of plants are now cultivated on a commercial scale—a very small proportion of the total known flora. The tendency is to reduce rather than increase the number, as the chemist learns how to synthesize plant products. Thus coal tar dyes supersede vegetable dyes, although coal tar is itself, ultimately, derived from vegetation ; and better varieties of wheat drive out inferior varieties. The increasing cultivation of herbs for the herb drug market perhaps restores the balance.

Apart from the staple cereal and fibre plants, and the various sources of such things as cellulose and timber, the most important economic crops to-day are : rubber, soya bean, quinine, tea, coffee, cocoa, sugar cane, banana, tung oil, varnish tree (Rhus), tobacco, opium, sisal and jute. The chief supply of nearly every one of these is now far from its original source, often in a different continent, as coffee, rubber, quinine and sisal. This has been brought about at the expense of the original vegetation, as a direct result of the growing economic interdependence of mankind. But it only became possible when the main features of the world's vegetation were known. It is obviously an advantage that all men who want tea or soap should be able to obtain these things, rather than that they should be confined to the few ; but mankind is going through a period of intense economic readjustment in order to achieve this desirable end of plenty of everything for all. There is a further conflict between what men need at any given level of civilization, and what 'interests' can persuade them to want.

The world is far from being botanically explored yet. But much of what remains to be done is predictable, thanks to increased knowledge. This enables us to carry on the work more systematically. There may not seem to be the same careless rapture in exploring a given region for largely predictable plants that there might be in wandering through unexplored worlds. But lack of knowledge is a real handicap. It is because we see the past world through eyes which have been opened that it looks romantic. To contemporary man the vegetation must have been confusing, exasperating and overwhelming. So far as plant exploration is concerned, the present is the age of the intensive specialized botanical explorer and the chemist.

PRESERVATION OF GEOLOGICAL RECORDS*

BY DR. M. MACGREGOR,

GEOLOGICAL SURVEY OF GREAT BRITAIN

THE preservation in a carefully documented and permanent form of geological records of all kinds is a matter which should be regarded as of the utmost importance, and the opportunity is taken here of stressing the need for conjoint action to deal with it. If the examples used by way of illustration are drawn entirely from Scottish sources, it is partly because they have come directly under my own observation and partly because the suggestions advanced may gain in cogency if their application to one particular region is emphasized.

The importance of preserving geological sections of outstanding or critical significance has long been recognized. These may be conveniently grouped into three broad, more or less arbitrary, categories. They may, for example, illustrate unique episodes in the history of the earth ; they may represent landmarks in the progress of geological thought or symbolize striking advances in our knowledge of geological processes ; they may, again, be sections that require re-examination and re-consideration from time to time in the light of modern research. For these and other reasons—historical, educational and scientific—the question of their preservation is a challenging one for all geologists.

These three categories may be very briefly dealt with. It would not be easy to select a more impressive illustration of the first of them than the little trial quarry at the roadside 3½ miles north-west of Inchnadamph, in Sutherlandshire (Geol. Surv. Photo. C. 2019). Here the basal beds of the Torridon Sandstone, containing wind-facetted pebbles, rest discordantly upon an eroded and weathered surface of Lewisian Gneiss. Not only does this section allow us a glimpse of a land-surface that existed in early Torridonian times, more than 500 million years ago, but also it illustrates clearly and diagrammatically the structural relations of two of the most ancient rock-formations known. It would be a great loss if the section were to be swept away during the road-widening schemes that are in contemplation, and assurances have been obtained that it will not be destroyed. Another striking example that may be adduced is the well-known "Fossil Grove" at Victoria Park, Whiteinch, now a museum under the care of the Parks Department of Glasgow Corporation (Geol. Surv. Photos. C. 3560–61).

---

* Substance of an address prepared for the Conference of Delegates of Corresponding Societies at the Dundee meeting of the British Association.

Of sections falling within the second category two instances may be given. The first of these is the historic exposure in the River Jed, near Jedburgh, discovered by Hutton in 1787 and described by him as providing unassailable evidence for elevation of the land, followed by erosion, subsidence and a fresh cycle of deposition. The originality of Hutton's genius is perhaps nowhere more fully exhibited than in his interpretation of the Jed River section. This exposure (Geol. Surv. Photo. C. 3494), which shows the nearly horizontal sandstones and marls of the Upper Old Red resting unconformably on highly folded Silurian rocks, was in danger of being overgrown and obscured, but now, owing to the generosity of Provost Veitch, it has been largely cleared of vegetation and debris and a pathway constructed to it. The second example which may be quoted under this heading is the striated rock-surface on the south face of Blackford Hill, Edinburgh, known as Agassiz' Rock (Geol. Surv. Photo. C. 2079). This also is of historic interest, since it was during a visit to the locality in the latter part of 1840 that Agassiz recognized the grooved surface as the work of glaciers. A number of years ago the Edinburgh Town Council, at the request of the Edinburgh Geological Society, agreed to protect the rock-face with a railing and to erect a commemorative tablet.

Within the third category may be fitly included various sections on the slopes of Arthur's Seat, Edinburgh, which have from time to time been re-interpreted in the light of increasing knowledge. Some of these, on Salisbury Craigs (Geol. Surv. Photos. B. 928–9), were at one time in danger of being quarried away, but the whole area of Arthur's Seat is now a national park under the custody of H.M. Office of Works.

Clearly, however, the preservation of important or critical sections is only practicable in a limited number of cases, and in this connexion brief reference may be made to the exposures of fossiliferous clays and sands which were laid bare about 1868–69 in Cowden (or Cowdon) Glen, Renfrewshire, during the construction of a railway line between Caldwell and Neilston. James Geikie, Croll, Bennie and other geologists who examined the excavations came to the conclusion that the fossiliferous beds, with their mammalian and other remains, were deposited between two distinct boulder clays and were accordingly interglacial in age. Craig, on the other hand, claimed: (*a*) that much of the 'upper' boulder clay was due to landslips at the side of the valley bringing down portions of the 'lower' boulder clay over the laminated material; and (*b*) that where it was definitely *in situ* above the latter it was of a gravelly nature (with lumps of the underlying sediments) and owed its formation not to the action of ice but to that of water. While the interglacial age of these beds is now generally accepted, Gregory and Currie in 1928, after a review of the available evidence as presented by earlier workers and a critical examination of the vertebrate remains, concluded that the deposits were "post-glacial and probably Neolithic in age". The question is certainly an important one in its bearing upon the Glacial and post-Glacial history of the region. It cannot be discussed here, but the Cowden Glen sections will serve as illustrations of ones which we would much like to re-examine in the light of later work.

Perhaps the most important aspect of the problem, however, concerns the preservation in a permanent form of geological records in general. Although much has been accomplished in this respect, it is certain that a systematic and co-ordinated effort to deal more fully with the problem is both essential and urgent. Much valuable geological information can be obtained from excavations made for various purposes connected with industrial and allied undertakings, from boring and mining developments, from tunnelling and quarrying operations, from roadway and sewage schemes, from factory and housing extensions, and from temporary exposures in constructional work of all kinds. The machinery for dealing with shafts and borings for minerals more than 100 ft. in depth is already in existence, but in regard to the other operations enumerated there is a wide field not covered by any co-ordinated activity.

Much of the information that might be derived from such sources is lost, or is available only in a form that is difficult, and indeed often impossible, to interpret. Engineers and foremen in charge of constructional work, surveyors, well-sinkers and the like have their own special tasks and their own aims in view, and they cannot be expected to provide records in the form and with the detail required by the geologist. It is surely the duty of the latter to see that the exact information he needs is carefully collected and made available for purposes of research. This is done in the case of borings for minerals, and it seems essential that it should be done systematically in regard to temporary sections of all kinds.

The importance of such investigations and of their repercussions not only on scientific but also on economic problems is not sufficiently realized, and the opportunities they offer for adding to our knowledge are too often neglected. Certainly they will often be of small importance individually, but collectively they may well amount to an impressive body of valuable geological data. Their significance in the preparation of detailed geological maps need not be stressed. Temporary excavations have contributed much to our knowledge of the geological succession and structure in different areas, notably, so far as Scotland is concerned, around Edinburgh and Glasgow. On the other hand, it would be easy to cite examples of temporary exposures which were not examined and about which little or no information is now available. The cumulative loss to geology must be very considerable, and it is in the hope of minimizing it that the problem is raised anew. In the past, the preservation of records has been left too much at the mercy of accident, and it would seem essential to establish, or try to establish, some definite system of efficient safeguards.

Thus there are two objects to keep steadily in view. The first of these is the preservation, wherever possible, of sections of outstanding or critical significance. In a number of cases this has been secured through the co-operation and assistance of public bodies, and geologists must feel deeply indebted to these for their action. Private assistance has, as already stated, come to our aid in the case of the Jed River unconformity, while acknowledgment should certainly be made of the generous action of Major-General J. W. Stewart, when in 1930 he conveyed to the ownership of the Royal Society of Edinburgh the ground at Inchnadamph on which the Peach and Horne memorial stands (Geol. Surv. Photos. C. 3550–51). Where preservation of important sections is possible, however, appeals for co-operation and assistance will come more effectively from a committee representative of geological opinion throughout the country. One other thing must be said in this connexion. It will not be out of place to suggest that geologists themselves are not always entirely free from blame in this matter, and that some restraint might be put on indiscriminate collecting at specially important and limited exposures.

The second and, in my opinion, the more urgent claim on our attention, is the preservation of carefully annotated records of exposures that are likely to be destroyed or to disappear, and of sections that are temporarily opened for examination. Included among the latter are excavations of all kinds as well as borings for whatever purpose these may have been sunk. The information they yield, scientific and economic alike, ought to be made available in a permanent and accessible form. To ensure this will require the active co-operation of geological and natural history societies and of university geological departments throughout the country, each responsible for a particular region and each reporting annually to a central organizing committee, either of the British Association or of the Geological Society. Brief abstracts of the work done in the different regions should be published at intervals, and these abstracts ought unquestionably to indicate where the fuller details are available, whether published or preserved in manuscript form. What is required is a register of new information derived from temporary sections and some system of ensuring that the full records, including any diagrams and photographs, are permanently retained. There is nothing extreme in this suggestion, and it ought to be possible to institute an efficient system of precautions against avoidable loss.

OBITUARIES

Sir Thomas Heath, K.C.B., F.R.S., F.B.A.

SIR THOMAS LITTLE HEATH, who died on March 16, was one of the most learned and industrious scholars of our time. He was born on October 5, 1861, the third son of Mr. Samuel Heath of Thornton Curtis in Lincolnshire. Sent to school at Clifton College, Heath went on with a foundation scholarship to Trinity College, Cambridge; and there, reading for double honours, he took a first in both parts of the Classical Tripos, and was twelfth Wrangler in 1882. Those years in Trinity are pleasant to look back upon. Henry Jackson was at his best; Acton, Glaisher and Robertson Smith intensified the atmosphere of learning; William Wyse, H. H. Turner, Henry Head and Alfred North Whitehead were among the undergraduates; James Gow was writing his "History of Mathematics"—a "convenient compilation", as G. J. Allman called it, but good enough to start Heath on the work of his life. He won his Trinity fellowship in 1885, as his eldest brother, R. S. Heath, afterwards professor of mathematics in Birmingham, had done two years before; and many years later the College awarded him its honorary fellowship, the most prized of all his many honours.

In 1884 Heath entered the Treasury, after heading the list in the Civil Service competition. He was a faithful servant, and, winning all the promotion open to him, rose to be permanent secretary of the Treasury and controller of the Civil List, conjointly with Sir John (afterwards Lord) Bradbury. After the War of 1914–18, when even the Treasury was greatly changed, Heath left it for the responsible but less arduous office of comptroller-general of the National Debt Office, which he held until his retirement in 1926; in the following year he published "The Treasury", a little volume of reminiscences of Whitehall. He was succeeded at the Treasury by Sir Warren Fisher; the two men had married sisters a few years before.

Heath was one of those fortunate men who live two lives in one, and enjoy both without neglecting either. Cayley was a busy London solicitor for many years, during which much of his finest work appeared; and Heath wrote one big and famous book after another, after the day's work in Whitehall was done. He took to Greek mathematics as an undergraduate; he came to be the acknowledged master of his subject in Great Britain, and to rank with Loria, Tannery and Zeuthen, next after Heiberg, the greatest Hellenist and historian of them all. While he was still an undergraduate, or very soon after, he wrote articles on Pappus and on "Porisms" for the "Encyclopædia Britannica" under Robertson Smith; and about the same time he published, in Henry Jackson and Ingram Bywater's *Journal of Philology*, a little paper on "The σ of Diophantus", an old puzzle which Heath succeeded no better in solving than others had done[*]. This and the article on "Porisms" were a foretaste of his first book, on "Diophantus of Alexandria", which came out in 1885, the year of his fellowship. This "youthful work", as Heath afterwards called it, won immediate acceptance, and ran out of print before long. It was written before Paul Tannery revised the text and redirected attention to the remarkable connexion between Diophantus and Fermat; twenty-five years later Heath republished the book, re-written in great part, with a long and admirable supplement on Euler and Fermat.

A year after his Diophantus, Heath published his "Apollonius of Perga" (1896), next year that on "Archimedes", and eleven years later (1908) his great three-volume edition of "Euclid". For "Archimedes" and for "Euclid" Heath had Heiberg's text to build on, save that the "Archimedes" lacked Heiberg's subsequent and very valuable discoveries. But with all due allowance for this, what great books these of Heath's are! No English editor had dealt with Apollonius since Halley two hundred years before, and even the received translations of Euclid were a hundred years old. To translate these books faithfully, and annotate them with all that had been most usefully written by Cantor, Bretschneider, Camerer and the rest, had been Heath's labour of love for years.

Heath had now dealt with Apollonius, Euclid and Archimedes, the three great "Greeks", who in Asia, Egypt and Sicily made the Golden Age of Greek mathematics; then he set to work to end and crown his labours with "A History of Greek Mathematics". It is a book not only for the mathematician but also for every scholar, for mathematics is the greatest of all the legacies of Greece. Of that Golden Age, of the dim Pythagorean times before, and of the later Silver Age, with Diophantus, Pappus, Ptolemy and the rest, we find all or well-nigh all we want to know in Heath's orderly and copious book. It has, doubtless, the *défauts de ses qualités*. Heath has little of the critical taste and gift of brevity which make Allman's book look like a little gem, after fifty years; nor had he Heiberg's fathomless erudition, deep as his own was; nor does he show, or ever want to show, much imagination or speculative curiosity. Like so many other classical scholars he never seemed to care about what Egyptians or Babylonians *may* have known or done; but when at last these great secrets began to be explored Heath became deeply interested, and he reviewed Otto Neugebauer's "Vorgriechische Mathematik" for Nature with full insight and appreciation.

There are yet other works of Heath's, and not a few. After finishing his "Diophantus" and before settling down to the "History", he wrote a book on that 'Copernicus of Antiquity', Aristarchus of Samos, led on to do so (as he says) by H. H. Turner, his comrade both at Clifton and at Trinity. Half of the book deals with Aristarchus; the other half is a sketch of Greek astronomy, from the starry heavens of Homer and Hesiod down to Plato and Eudoxus, then on more briefly to Hipparchus and Ptolemy.

I think that Heath was at his best when he dealt, encyclopædically, with the life and work of individual men. As a historian he was more sober than a man need always be; he lacked colour, and was afraid of imagination. He found even Paul Tannery "prone to run away with an idea", and *ex abundante cautela* is a tag I have heard him use and recommend. He might have told stories, even about I.47, which would have helped to lighten the three volumes of his "Euclid". But this was not Heath's way. He was a quiet, patient scholar, rejoicing in the things which mattered to him, and which, after all, are the things which matter most to all lovers of learning. Not many years ago he brought out a pretty little volume containing the Greek text of Euclid's first book. The introduction and notes are interesting, but I find the short preface still more so, in which he talks of the "thrill of pleasure" with which he first cast eyes on the Greek text, in the days when he was young and when that text was extant only in old and rare editions. Now he has brought this and many another famous book within reach of us all; and in doing so he has left us an example of sixty years of unstinted and unwearied work, all done for the mere love of it.

D'Arcy Wentworth Thompson.

---

[*] The Diophantine equations hark back, as Heath explains, to the *hau*, or *heap*-calculus, of the Egyptians, and I suggested long ago that the Diophantine σ, answering to our x, might stand for *σωρός*, a *heap*. But Heath saw reasons to the contrary.

Sir Patrick Laidlaw, F.R.S.

SIR PATRICK LAIDLAW died on March 19 in his fifty-ninth year. His death is a major loss to medical science and a most grievous blow to all those who were privileged to know him personally.

Patrick Playfair Laidlaw, the son of Dr. R. Laidlaw, who was medical officer in the Seychelles, was born on September 26, 1881. A family removal to Cambridge enabled him to enter the Leys School, and from school he proceeded to St. John's College with a scholarship. He completed his medical course at Guy's Hospital and graduated B.Ch.(Camb.) in 1907.

Whilst still a student at Cambridge, Laidlaw gave evidence of his remarkable gifts for research by the publication of several papers on anatomical subjects and one outstanding piece of work on blood pigments. After a few years as demonstrator of physiology at Guy's, he joined the staff of the Wellcome Physiological Research Laboratories, and there, during the next five years (1909–14), he published, either alone or with his colleagues, more than a score of papers on pharmacological subjects, the best known of which is the classical work on histamine, carried out in collaboration with H. H. Dale. This happy and fruitful association with Dale was temporarily broken in 1914 when Laidlaw returned to Guy's as lecturer in pathology, but was renewed in 1922 when he was invited to rejoin the staff of the National Institute for Medical Research. Although never very happy in his academic teaching posts, Laidlaw's strenuous war years at Guy's had helped to give him the remarkable depth and width of knowledge in several medical sciences, which rapidly bore fruit in the new environment. He collaborated in important protozoological and biochemical investigations, but it is for his pioneer researches on virus diseases that he will be most especially remembered.

Laidlaw's study of canine distemper in collaboration with G. W. Dunkin will long remain a model for those engaged in virus research. In a series of papers they described the pathology of the disease in dogs and ferrets, brought forward irrefutable proof that the disease agent concerned is a filterable virus, and finally reported the successful immunization of dogs and ferrets by means of formolized virus vaccines. The outstanding importance of this work was immediately recognized and their method of prophylaxis adopted in veterinary practice.

His next major research was on influenza. Together with C. H. Andrewes and Wilson Smith he succeeded, in 1933, in isolating a virus from patients. This discovery provided a new basis from which to attack the many problems presented by epidemic influenza, and Laidlaw with his colleagues spent the next three years in laying the foundations of our newer knowledge of the disease. On his appointment as deputy director of the National Institute in 1936, he took a less active share in the influenza work but remained always at the service of those who carried it forward. On the outbreak of the War he turned with fresh enthusiasm to new virus problems, and continued working at them until the day of his death.

Laidlaw's work brought well-deserved recognition in his later years. He was elected a fellow of the Royal Society in 1927, was awarded its Royal Medal in 1933, and was elected F.R.C.P. in 1934. The following year he was honoured with knighthood. Shortly before his death he became an honorary fellow of his old college, St. John's, Cambridge.

It is not, however, as a famous man that Laidlaw will be mourned by those who knew him well, but as a wise and ever-helpful colleague, a generous and most loyal friend. Of a shy and reserved disposition, he shunned the limelight and detested anything which savoured of self-advertisement. His keen critical faculty was at the service of those who sought his advice, but was most constantly directed against himself and his own work. His curiosity had no bounds and urged him to incessant probings in new directions, so that his 'unsuccessful' experiments were a constant stimulus and source of inspiration to those around him. Well might he have said with Leeuwenhoek, "The work which I've done for many a long year was not pursued in order to gain the praise I now enjoy but chiefly from a craving after knowledge." W. S.

Prof. E. Branly

PROF. EDOUARD BRANLY, the inventor of the coherer, which enabled Marconi to develop wireless communication and who is known in France as the 'father of wireless', died on March 25 at the age of ninety-five. He was born at Amiens on October 23, 1844, and after showing great brilliance as a schoolboy entered the École Normale. In 1868 he became a professor at the Lycée of Bourges.

Branly's bent, however, was for research work. He therefore went to the Sorbonne and took up work in the physical laboratory and began his study of electricity and magnetism. He was a poor man, and in order to become self-supporting he qualified as a medical man and practised medicine for about twenty years, spending all his spare time in electromagnetic research, for which he received the degree of doctor of science. In 1873 he went to the Institut Catholique in Paris, where he set up a small laboratory, and it was here that his investigations led to the discovery that the electrical resistance between loose particles of metal, such as iron filings in contact with one another, diminishes under the influence of electric action.

In 1872, Branly published a paper on the "Measurement of the Intensity of Currents by the Electrometer"; in 1892, one on "The Electrical Resistance at the Contact of Two Metals", and in 1893 one on "The Property of Discharging Electrified Bodies Produced in Gases by Incandescent Bodies and by Electric Sparks" and in the same year, one on the "Resistance of Thin Metallic Films". The last four of these papers were published in abstract in the *Journal of the Institution of Electrical Engineers*.

Branly made a series of observations into the variations of conductivity of a large number of materials under varying electrical influences. He found that substances which responded best to the phenomenon of sudden increase of conductivity were iron, copper, brass, aluminium, zinc and similar metals. He discovered also that the conductive effect on metallic filings, caused by a nearby electrical discharge, persists for a comparatively long period, but disappears rapidly if subjected to a shock. He obtained the required result by tapping the tube in which the filings are contained. In this way he discovered a principle which was adopted in the original Marconi system. Marconi was very grateful for the help he had received from Branly. He acknowledged this help in his first cross-Channel marconigram in 1899, which was addressed to Branly. It read as follows: "Marconi sends M. Branly his respectful compliments across the Channel this fine achievement being partly due to the remarkable researches of M. Branly."

In 1889 Lodge showed that if two small metal spheres were arranged so that they were nearly touching and separated only by a very minute film of air, the current from a small battery was unable to pass between them. This was proved by the fact that no reading was observable when a sensitive galvanometer was placed in a circuit between them. When, however, a Leyden jar was suddenly discharged in their vicinity, the air film was broken down and they cohered, making electrical contact with one another and allowing a current to pass through the galvanometer. This experiment was described in the year 1890 before the Institution of Electrical Engineers and an account of it appears in the *Journal*. In 1890, Prof. Branly proved the very important fact that filings could be made to cohere by an electric discharge taking place in their vicinity. He described his researches in "La Lumière Électrique" (May and June 1891), and he showed that metal filings could be decohered by a slight concussion. Lodge realized the importance of this fact. He introduced modifications in the Branly coherer and improved its sensitiveness considerably.

Lodge exhibited his apparatus in 1894 before the British Association at Oxford, and received signals at a distance of 150 yards. At the time, the idea did not occur to him that this instrument might be turned to practical use for long-distance radiotelegraphy. In 1902 Branly made another coherer in the form of a tiny tripod, having steel points at the end of each leg. He stood this upon the surface of a flat plate of steel. Under normal conditions no current passed between the tripod and the plate, but in the presence of the Hertzian wave coherence took place. He arranged his recording apparatus in such a way as to jar the plate immediately the wave had passed, thus effecting decoherence.

Throughout the rest of his long life, Branly went steadily on with research work on wireless waves and made a number of discoveries which he communicated at various times to French scientific bodies. He also wrote a number of papers which appeared in the *Comptes rendus* of the Paris Academy of Sciences. Even after the outbreak of War he remained at work in Paris, but in October, yielding to the persuasion of his family, he returned to the country. He was made a Grand Officer of the Legion of Honour and received many foreign distinctions.

Dr. A. G. Jacques

In the field of experimental cell and general physiology the name of Alfred George Jacques had become increasingly prominent during recent years. *Science* announces that Jacques died by drowning on February 20, 1939—and to many readers of NATURE this news, already a year old, must come with the shock of surprise and it will occasion widespread regret among experimental biologists.

Though A. G. Jacques was born in England at Sutton, Surrey, on April 18, 1896, he was educated mainly in Canada, later obtained the Ph.D. degree at Harvard, and his name rightfully attained prominence from his work at the Rockefeller Institute for Medical Research. In fruitful collaboration with Dr. W. J. V. Osterhout, Jacques' early work was devoted to problems of cell physiology, using the large vesicles of Valonia and Halicystis as experimental material. These fascinating organisms still claimed his attention until his death which, it is learned, occurred at Bermuda, where he had conducted much of his experimental work. Theoretical and experimental works mainly published under his name, in the *Journal of General Physiology*, present an impressive record of a career so prematurely ended.

Jacques investigated the mechanism which regulates the composition of the sap of the large vesicles which he studied—he accepted the challenge which the outstanding accumulation of inorganic salts in plant cells presents—and his name will be identified with theories of salt absorption based on the view that salts enter cells in the form of undissociated molecules. This view arose from an ingenious series of experiments, in which Jacques collaborated, which showed that certain weak electrolytes (H_2CO_3, H_2S, NH_4OH, etc.) penetrate most readily as neutral molecules, and, therefore, their entrance into the sap was controlled by the pH relations of sap and external solution. This novel idea was extended by Jacques in his later work to embrace the entrance of the alkali metals into cells. A steady stream of papers, both theoretical and experimental, appeared under his name. It would be idle in short space to summarize his work; neither should we declare that he had reached his final goal; but the distance he had travelled in a few years of active work is the measure of the loss which science sustains by his untimely death. The challenge of the problem to which Jacques devoted himself still remains—those who take it up where he perforce relinquished it will long recognize his worth and regret his passing.

F. C. STEWARD.

WE regret to announce the following deaths:

Sir James MacKenna, C.I.E., formerly agricultural adviser to the Central Government of India, and director of the Agricultural Research Institute, Pusa, on April 3, aged sixty-seven years.

Dr. Oran Raber, plant physiologist and conservationist to the U.S. Forest Service, on February 29, aged forty-seven years.

NEWS AND VIEWS

Scandinavia

AUSTRIA, Czechoslovakia, Poland, Finland, and now Denmark and Norway have been attacked in turn by the reactionary forces of Europe. By sheer weight of numbers and over-powering military forces the totalitarian war machine is proceeding on its way, leaving as it passes a trail of physical and spiritual destruction. The University of Copenhagen includes the world-famous Institute of Physics presided over by Prof. Niels Bohr, For.Mem.R.S., whose genius has been responsible for much of our present knowledge of atomic physics. A letter from his Institute appears elsewhere in this issue. Prof. G. Hevesy, For.Mem.R.S., has worked there for the past few years. Prof. August Krogh, For.Mem.R.S., also of the University of Copenhagen, has an international reputation for his studies in animal physiology, and Prof. Boysen Jensen is equally well known for his work on plant physiology. There is also the famous Carlsberg Institute, whence much fundamental work on biochemistry has come. The name of Prof. Th. Mortensen, the distinguished zoologist and oceanographer, will also be associated with the Carlsberg Institute. Prof. N. E. Nørlund, For.Mem.R.S., director of the Danish Geodetic Institute, is known to mathematicians, astronomers and geodesists.

Norway has an active University at Oslo. Meteorological investigations initiated by Prof. V. F. K. Bjerknes, For.Mem.R.S., are the basis of modern weather forecasting. Prof. J. Hjort, For.Mem.R.S., is well known as a marine biologist; Prof. C. Størmer's work on the aurora will be familiar to many readers of NATURE. Prof. L. Vegard is a well-known astrophysicist on its staff; a letter signed by him also appears in our pages this week. The publications of the Bergen Museum are widely known. It is worth remarking that the names mentioned above include no fewer than six foreign members of the Royal Society. It cannot be expected in present circumstances that scientific work will proceed in these and other institutions in Denmark and Norway. Whether they take an active or a passive part in the present struggle, the peoples of these two countries will have the support of all who believe in the fundamental principles of academic and individual freedom.

Dr. S. Zuckerman

IN April 1939 Dr. S. Zuckerman was appointed to the chair of anatomy in the University of Birmingham, and plans were immediately discussed for the establishment in the Department of Anatomy of an experimental unit in order to allow the new professor to continue and develop the programme of work on which he has been engaged for some years. Unfortunately, the War has interrupted these discussions, and the plans have necessarily been shelved for the moment. In view of this, and also because Dr. Zuckerman is engaged in war work elsewhere, he has had to postpone the assumption of his appointment at Birmingham until more propitious times. Meanwhile Dr. C. F. V. Smout is the acting head of the Department of Anatomy at Birmingham. Dr. Zuckerman entered on his academic career as a medical student of the University of Cape Town. After spending two years there as a demonstrator of anatomy he came to London as a Union Research Fellow, and qualified in medicine from University College in 1928. During 1928–32 he was research anatomist of the Zoological Society of London. During 1933–34 he worked in the United States, first as a research associate in the Primate Laboratories at Yale and afterwards as a Rockefeller Fellow. On his return to England he joined Prof. Le Gros Clark at the University of Oxford as a Beit Fellow and Departmental demonstrator. Later he was appointed University demonstrator and Nuffield research worker in endocrinology, and he continues to hold these appointments for the present. While at Oxford Dr. Zuckerman has played an important part in the development of research laboratories of a modern type in the Department of Human Anatomy.

Dr. Zuckerman's first work was concerned with the processes of development and growth in monkeys and apes, and with the mechanisms underlying the social behaviour of these animals. Many of his early researches were incorporated in his books "The Social Life of Monkeys and Apes" and "The Functional Affinities of Man, Monkeys and Apes". These behavioural studies led him on to an inquiry into the reproductive mechanisms of primates—particularly the menstrual cycle and its control by hormonal and neural factors. This again, from observations on the relation of changes in water metabolism to the menstrual cycle, has turned his attention more recently to the problem of the interrelation of the adrenal glands and the gonads. Dr. Zuckerman has also published a number of papers dealing with the prostate gland and other male accessory reproductive organs, as well as the histogenesis of tissues which are sensitive to œstrogenic stimulation.

Gold Medallist of the Society of Antiquaries

THE Gold Medal of the Society of Antiquaries of London, which is regarded by archæologists as the highest mark of recognition of distinguished service to their science, has been awarded for the year 1940 to Aarne Michel Tallgren, professor of the archæology of Finland and the North in the University of Helsinki, for his studies in the prehistory of the Eurasiatic continent, with more especial reference to the development of culture in the northern regions of that tract. For more than thirty years his studies have been devoted to the elucidation of the broader problems of this field, upon which he has brought to bear a vast knowledge of detail combined with unfailing judgment and soundness of inference.

Since the close of the War of 1914–18, Prof. Tallgren's publications dealing with the archæology and cultural history of Finland and adjacent regions of the northern tract have brought him an outstanding reputation as an international authority on the study of European prehistory. An even greater service to archæological studies has been rendered by his periodical publication, *Eurasia Septentrionalis Antiqua*, which he founded in 1926 and edited, contributing liberally to the contents himself until, in 1939, the action of the Soviet Government, by cutting his line of communications with Russia, deprived him of the material essential to the continuation of his studies and constrained him to stop publication (see NATURE, 144, 971 ; 1939). This action of the Soviet followed Prof. Tallgren's account of conditions in Russia in his "Archæological Studies in Russia" (1936).

Epidemiology of Evacuation

IN his presidential address to the Section of Epidemiology and State Medicine of the Royal Society of Medicine on April 5, Dr. J. A. Glover, chief medical officer of the Board of Education, stated that in the evacuation carried out in Britain last autumn there were moved 1,270,000 persons, made up as follows : 734,883 school children, nearly all moved in the first two days before the beginning of war ; (2) some 260,300 young children accompanied by (3) some 166,200 mothers and other adults ; and (4) 12,291 expectant mothers. All these persons were moved with punctuality and precision without a single casualty in four days. As regards the incidence of infectious disease, the record of the first four months was extraordinarily good. The cases of diphtheria and scarlet fever notified were only two thirds of those which occurred in the corresponding period of 1938, and the cases of poliomyelitis were only one third, although all these three diseases had their seasonal maxima in autumn and were diseases to which school children were particularly liable. There was a decline in notifications of puerperal pyrexia.

There had been small epidemics of enteric fever before evacuation took place, but notifications afterwards fell, and in November and December were well below those of 1938. The expected epidemic of measles was not realized and particularly avoided the big cities, and especially London. The health record of evacuated special schools was very good. The comparative freedom from infectious disease was attributable to the careful preparations of the Ministry of Health, the good work of the medical and nursing services, the care of the foster parents and teachers, the general soundness of the environmental hygiene, and the splendid weather of the early autumn. Dr. Glover maintained that the general policy of dispersal in billets was preferable to that of concentration in camps, in view of the much greater risk of spread of disease in such concentrations of children. In conclusion, he stated that the evacuated child who remained in the reception areas benefited greatly in health.

National Union of Students: London Medical Committee

THE London Medical Students' Committee of the National Union of Students was formed shortly after the War began. The first important action which the committee took was to get the status of medical students defined by the Ministry of Health. Up to this time hospital authorities and the Ministry of Health both disclaimed responsibility. The position is now clearly that medical students have no obligations to the Ministry, and vice versa. A request was received recently from one of the northern universities that the London Committee should organize a conference on medical student life and work. The Committee is accordingly arranging a meeting to discuss the teaching of medicine and the methods of study, which, it is hoped, will be held in a Midland university in May. The conference will be divided into three main sections. The first part will be devoted to the pre-clinical student, the second to the clinical student, and the third to the newly qualified doctor.

There has been much discussion in the Press recently on reforms in medical education. Efficient teaching is no less necessary now than it was before the War ; in fact, with the prospect of courses being shortened, efficient teaching becomes even more necessary. The conference will therefore have two sessions on education in all its phases, and from the experience of delegates endeavour to formulate an improved scheme of medical teaching. This will be combined with an endeavour to assure to the newly qualified medical man adequate house appointments to make him fit to carry out his duties. Medical students have suffered as much as others from many recent hasty decisions, and the prompt response to attempts to cut out subjects (for example, pathology from the Conjoint Board Examination) from the curriculum has shown a very healthy feeling on the part of students that standards must not be lowered, and was perhaps instrumental in maintaining the standard of the curriculum. The medical practitioner has certain duties to the public, and therefore his qualifications must be such as to enable him to carry out these duties, whether in war-time or in the time of peace.

Pharmacopœia Revision

DR. C. H. HAMPSHIRE, secretary of the Pharmacopœia Commission, gave an account of the work which is being done in preparation for a new "British Pharmacopœia" in a lecture delivered at an evening meeting of the Pharmaceutical Society on April 9. He confirmed that the Commission hopes to provide standards not only for crude drugs and chemicals but also for as many galenical preparations and compounded drugs as possible, adding that it is essential that standards for such substances should have due regard to the possible loss of active matter during manufacture and subsequent storage. The greater part of the lecture was devoted to an exposition of recommendations made by various committees for the inclusion of new substances in the next "Pharmacopœia". Dr. Hampshire exhibited specimens of these substances, classifying them in their appropriate groups. With regard to vitamins, he said the principal preparations of this group recommended for description are: Standardized concentrated solutions of vitamins A and D; a vitaminized oil standardized to contain vitamins A and D in the proportion contained in a good average specimen of cod liver oil; halibut liver oil containing not less than 30,000 units of vitamin A per gram; and pure crystalline aneurine hydrochloride to replace the adsorbate of vitamin B_1, described in the "Addendum, 1936".

Dr. Hampshire explained the reasons for some of the proposed additions to the "Pharmacopœia". Thus mandelic acid and calcium mandelate are both in use in the treatment of urinary infections; sulphanilamide is recommended as the best known member of the sulphonamide group which is free from patent complications; parachlorometacresol is recommended for use as a bactericide in sterilizing solutions for injection, and as a bacteriostatic preservative in certain solutions. He said that the proposed inclusion of the sera and other biologically tested preparations is necessary in order to bring this section of the work of the "Pharmacopœia" up to date. In this field the "Pharmacopœia" is kept closely in line with the regulations under the Therapeutic Substances Act; the regulations provide for the control of biologically tested substances in Great Britain and Northern Ireland, while the "Pharmacopœia" extends the control to other parts of the British Empire in which the "Pharmacopœia" is accepted as a legal standard. The revision has included a full review of all analytical procedure described in the various monographs and in the appendixes. In two directions a considerable increase in analytical methods is proposed: (*a*) the addition of new tests and assays for galenical preparations and compounded drugs; and (*b*) the addition, in a number of instances, of assays for the alkaloidal content of salts of various alkaloids.

Astronomical Investigations of Horrox

PROF. F. J. M. STRATTON has published a very interesting and full account of the work of Horrox (*Occas. Notes Roy. Astro. Soc.*, No. 7; 1939). To many astronomers, Horrox's fame rests almost entirely on his observation of the transit of Venus on November 24, 1639 (O.S.), his own calculations having shown an error in the Rudolphine tables, and also that a transit should take place on the above date. This was only a small part of his work, for, in addition to improving the tables then in existence, he was the first to show that the moon's orbit around the earth is an ellipse, the earth being at a focus. An excerpt from some of his writings at the age of eighteen shows that he anticipated Newton in connecting the movements of the planets with that of a body falling to the earth. The motion of the line of apses was explained by Horrox as due to the disturbing effect of the sun, and he was able to illustrate the idea by a simple pendulum experiment. In addition to his explanation of other difficulties connected with the motion of the moon, he detected the long inequalities in the opposite sense in the motions of Jupiter and Saturn, and he showed that comets move in elliptic orbits around the sun.

Although he undertook regular observations of the tides, no published work of Horrox on this subject survives, but he expressed the hope to Crabtree less than a month before his death that he would shortly detect the secret of the tides. Kepler's value of the distance of the sun was 3,500 times the earth's radius, and Horrox gave the value as 15,000, that is, about two thirds the correct value. It is amazing that Newton adopted 5,000 fifty years later, instead of using Horrox's 15,000. When it is remembered that these results were obtained by one who had only attained the age of twenty-one and that he was practically self-taught and unaided, it is not surprising that astronomers have kept his name in affectionate remembrance for hundreds of years. What fields would Horrox have explored if he had not died at the early age of twenty-two in 1641, the year before Newton was born? In 1874, when a transit of Venus occurred, a memorial was erected to him in Westminster Abbey, and over the monument are carved the words in which Horrox reported that he had abandoned the observations of the sun to carry out his spiritual duties in the Church.

King Psusennes's Tomb at Tanis

Now that the jewellery associated with the sarcophagus of King Psusennes at San el Hagar, in Lower Egypt, has been removed to the Cairo Museum, further details are becoming available which serve to indicate more fully the cultural and historical significance of the find. The similarity in the circumstances of discovery with those of the discovery of the tomb of Tutankhamen is striking. For years Lord Carnarvon and Howard Carter excavated in the Valley of the Kings without notable success until they made their great discovery. At Tanis, which had already been explored by both Mariette and Petrie with indifferent results, Prof. Montet pursued his investigation of the relics of the obscure Twenty-first and Twenty-second Dynasties for nine years from 1929, before last year he made the remarkable discovery of the gold and silver sarcophagus of King Shishak, of the Twenty-second Dynasty, in the otherwise rifled tomb of King Psusennes, of the Twenty-first Dynasty.

The tomb of Psusennes, son of Smendes, founder of the Twenty-first or Tanite Dynasty, is situated in the temple of Rameses. It is of solid rose granite, it is stated in a communication from the correspondent of *The Times* in the issue of April 6, and is a few metres underground. Entrance is at present down a shaft about four metres deep through rock and sand. A small anteroom leads by a short passage, about two metres long, and hewn through solid granite, into the funerary chamber. This is also small, measuring only seven metres long by about three metres wide and high. The sarcophagus itself is 3½ metres long, and not less than 2½ metres wide. An unusual feature of the outer sarcophagus is the decoration on both the upper and under surface of the cover. On the upper surface is a full length image of the king dressed as Osiris. Broken features of the image of the inner sarcophagus suggest that it was damaged when being introduced into the tomb.

Antiquity: a Sutton Hoo Number

Antiquity of March last is devoted to a detailed account of the discovery, excavation and finds of the Sutton Hoo ship-burial. The excavation is described by Mr. C. W. Phillips, who points out that until 1939 the archæology of Britain in Anglo-Saxon times has had to concern itself little with either ship-burials or to a great extent with rich burials of any kind, for omitting those of Kent, and a few important burials at Taplow, Broomfield and elsewhere, the most striking feature of Anglo-Saxon graves is their almost universal poverty. In the more detailed description of the finds Mr. T. D. Kendrick gives accounts of the gold ornaments, the large hanging bowl and the jewellery; the silver is described by Mr. Ernst Kitzinger, and a summary account of the coins is contributed by the editor, Mr. O. G. S. Crawford. Mr. W. F. Grimes is responsible for a description of the methods followed in salvaging the finds, "an exciting and exacting task, extending over more than a week", in which he was first called to participate when the gold purse and its trappings had been found. Serious problems were presented by corrosion, but their solution called for no new and elaborate technical methods, but rather the application of simple readily available means to deal with an unexpected range of materials, each apart from the gold objects with its own set of problems. The identity of the individual whom the mound and its contents commemorated is discussed in full detail by Dr. H. Munro Chadwick, who accepts the possibility that it may have been the cenotaph of a king lost at sea—the editor of *Antiquity* here points out that there never has been question of a burial. After discussion of the various possibilities Dr. Chadwick elects for Redwald (*ob. c.* 624–5) as the most probable. The series of photographs accompanying these contributions constitutes a valuable record of this notable find.

Indian Farming

THIS new monthly magazine, issued by the Imperial Council of Agricultural Research, replaces the bi-monthly *Agricultural and Livestock in India*, published by the Council since 1931. The aim of *Indian Farming* is to present scientific information in a popular form, and to form a link between the research worker and the cultivator. The format of the new journal is more pleasing than that of its predecessor and should appeal to a wider public. The contents include original articles on agricultural science, short notes on selected research work, reports from research stations, "answers to correspondents", practical hints to farmers, and book reviews. The popularization of agricultural science is a task as difficult as it is important, and the editorial committee is to be congratulated on its good beginning in seeking the happy mean between over- and under-simplification. The first article, by Sir Jagdish Prasad, on agricultural research in war, puts in a timely plea for the continuation of pure research during a period of stress when the demands for immediate results are most pressing.

Fluorescent Enamel Paints

THE Continental Lithograph Corporation, 952 East 72nd Street, Cleveland, Ohio, has put on the market a series of 'enamel paints' (Conti-Glo Fluorescent Lacquer Enamels) with which brilliant fluorescence effects can be obtained when they are illuminated by radiation in the 'near ultra-violet'. Such a radiation can be conveniently obtained from tungsten filament lamps having bulbs of 'black' glass; these are supplied by the same Company. They are mounted in aluminium reflectors in order to concentrate the ultra-violet energy on the enamelled surface.

Tested with a mercury vapour lamp screened by a plate of ultra-violet transmitting glass, the samples appear to justify the maker's claims. The colours include white, pink, and orange, with various yellows, greens, and blues. Moreover, the fluorescent hue is markedly different in some cases from that of the paint in ordinary light; thus a cream paint becomes a green in the ultra-violet and a rose colour fluoresces red, while a white becomes a blue. These enamels have interesting possibilities for entertainment and decoration. They are said to be easily applied by ordinary spraying and brushing methods, and can even be applied (diluted with lacquer-thinner) to fabrics.

Saliva Superstitions

THE December issue of *Folk-Lore* contains a richly documented article on this subject by Miss Rachel Sclare, of Leeds, who illustrates the medicinal and curative properties attributed to saliva throughout the ages and different parts of the world by quotations from the New Testament, the writers of classical antiquity (Theocritus, Tacitus and Pliny), the Middle Ages (Hildegarde of Bingen, Maimonides, and Albertus Magnus), and modern times (Brand, Tylor and Frazer). The diseases for which saliva has been used both as a curative and less frequently as a prophylactic measure are numerous, and include sore eyes, blindness, rheumatism, headache, toothache, warts, burns, wounds, etc. As a prophylactic, saliva has been employed as a protection against infectious diseases and as an antidote to poisons, as well as a means of averting ill-luck. The belief in the magical properties of saliva, which still flourishes not only in primitive races but even in England as well as in other civilized countries, appears to be founded on the supposition that this secretion possesses a vital force closely connected with man's blood and the whole of his person.

The Bed of Procrustes

A WITTY and amusing paper with this title was read by Mr. Gordon D. Knox before a meeting of the Tenterden Toc H (Tenterden: K. P. Press, 1940. 1*s*.).

It will be recalled that, in Greek legend, Procrustes made all travellers who visited him lie on a bed of fixed length, stretching their limbs if they were too short and lopping them off if they were too long. Mr. Knox suggested that this treatment, although murderous when applied to human beings, is beneficial when applied to problems. It is a great advantage to make a wide range of problems conform to one fixed type, namely, that usually known as the method of ratio or proportion. Examples were given of applications to arithmetic, algebra, geometry and applied mathematics.

Books on the History of Science and Medicine

CATALOGUE 55, recently issued by E. P. Goldschmidt and Co., 45 Old Bond Street, W.1, is devoted to bibliography and reference books, particularly those dealing with the history of science and medicine. Attention may be directed to the following items: A. Claudius's "Histoire de l'imprimerie en France" (1900–1914), Du Cange's "Glossarium mediæ et infimæ Latinitatis" (1883–1887), Thomas James's "Catalogue of the Bodleian Library" (1620–1635), J. S. Bailly's "Histoire de l'Astronomie ancienne—Histoire de l'Astronomie moderne—Traité de l'astronomie Indienne et Orientale" (1781–1787), L. Choulant's "Handbuch der Bücherkunde für die aeltere Medizin" (1828), John Ferguson's "Bibliographical Notes of Histories of Inventions and Books of Secrets" (1883–1916), John Leland's "Laboryouse Journey and Serche for Englandes Antiquitees" (1549), and Andrew Borde's "Fyrst Boke of the Introduction of Knowledge" (1548).

Aftershocks of the Great Turkish Earthquake

As anticipated by the seismologists at the Istanbul Observatory, aftershocks of the great Turkish earthquake of December 27 (NATURE, January 6, p. 13) still continue, and these have been accompanied by floods possibly due to changes of land-level occasioned by the shocks. The region most affected recently has been near the scene of the original disaster. On April 3, two violent earthquake shocks occurred in the region of Amasya in Anatolia. No casualties are reported. Following torrential rains, the Yesil Irmak and the Tersakar Dere burst their banks, flooding wide areas, including the famous apple orchards near Amasya, and also inundating about thirty villages, some of which have had to be abandoned. Twenty-five villages were cut off by the floods. No casualties have been reported.

Cerebro-Spinal Fever

CEREBRO-SPINAL fever, caused by infection with the meningococcus, was epidemic in Great Britain in 1931 and 1932, some 2,200 cases being notified in each year. The number of cases then declined, and in 1935 and 1936 the annual total was about 900. Since then there has been again a rise, to 1,500 cases in 1939. In the first seven weeks of this year there were 1,753 cases, and 623 new cases were notified in the week ending March 2. In view of the prevalence of this epidemic, the Ministry of Health has issued a "Memorandum on Cerebro-Spinal Fever" (Memo. 234/Med. H.M. Stationery Office. 2*d.* net). It discusses the epidemiology of the disease, the control of contacts (who may be carriers of the meningococcus) and diagnosis, and describes the treatment and general measures of prevention. Formerly, the administration of anti-meningococcal serum was the only specific treatment, and is still desirable in the very acute cases. Treatment has, however, now been revolutionized by the use of the drugs sulphapyridine and sulphanilamide, and full directions are given as regards dosage and method of administration.

Announcements

PROF. WALTER W. STEWART has been elected to succeed Mr. John D. Rockefeller, jun., who has retired from his position both as chairman and as member of the Board of the Rockefeller Foundation. Prof. Stewart, who is fifty-five, was during 1928–30 an economic adviser to the Bank of England. In 1931 he was appointed American member of the special advisory committee to the Bank for International Settlements. He is a professor of economics at the Institute for Advanced Study at Princeton University.

THE Ettore Marchiafava Prize, founded by the University of Rome on October 28, 1938, for the best work on morbid anatomy or general pathology, has been awarded to Profs. Mario Monacelli, director of the clinic for dermatology and syphilis at Messina, and Giulio Raffaele, of the University of Rome.

AT the recent annual general meeting of the Institute of Metals, held in London, the following officers were elected: *President*, Lieut.-Colonel the Hon. R. M. Preston; *Vice-Presidents*, Dr. S. F. Dorey, Engineer Vice-Admiral Sir George Preece and Mr. A. J. G. Smout; *Treasurer*, Lieut.-General Sir Ronald Charles; *New Members of Council*, Dr. W. E. Alkins, Mr. G. L. Bailey, Captain F. C. Braby, Colonel P. G. J. Gueterbock, and Prof. D. Hanson.

AN after-luncheon lecture will be given at the Chemical Club, 2 Whitehall Court, London, S.W.1, on April 15 by Mr. Arthur Elton, who has taken for his title "The Interpretation of Science by the Film". Mr. Elton is at present at work on the Government scheme, initiated by Sir Kenneth Clark, of propaganda films of a technical nature.

A CONGRESS of Forensic Medicine, Insurance and Criminal Anthropology will be held at Naples during May 30–June 1. Further information can be obtained from the general secretary, Prof. Gennaro Punzo, Via Luciano Armanni 3, Santa Patrizia.

ACCORDING to a census on June 30, 1939, the total aboriginal population of Australia was 77,269, including 25,712 half-castes. Nearly half the total full-blooded natives were in Western Australia. In New South Wales there were only 794.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

IN THE PRESENT CIRCUMSTANCES, PROOFS OF "LETTERS" WILL NOT BE SUBMITTED TO CORRESPONDENTS OUTSIDE GREAT BRITAIN.

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 593. CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

The Mass Centre in Relativity

THE question whether there exists in relativity mechanics a theorem analogous to the classical law for the motion of the mass centre (conservation of total momentum) has, as far as we can see, never found a satisfactory answer. Eddington[1] has taken this fact as the starting point for a general attack against the usual application of wave mechanics to fast-moving particles without contributing himself anything positive to the question. The reason why this problem has never been seriously treated seems to be this.

In classical mechanics the internal potential energy depends on the simultaneous relative positions of the particles; therefore one can separate the relative motion from the translatory motion of the centre. In relativity, however, all forces are retarded, the interaction does not depend on simultaneous relative positions and the separation of the relative motion from the translation of the whole system loses its meaning.

Quantum mechanics circumvents this problem by considering interactions as produced by emission and reabsorption of other particles. We were induced to reconsider this problem by its bearing on a relativistic and 'reciprocal' formulation of second quantization. Without touching this question, we shall state here some simple results concerning free particles. It is clear that in this case there must exist a 'rest system' Σ°, that is, a Lorentz frame in which the total momentum vanishes. The problem is to describe the relative motion in an invariant way.

We start by bringing the classical derivation into a form permitting generalization. If $\mathbf{r}_1$, $\mathbf{r}_2$ are the position vectors, $\mathbf{p}_1$, $\mathbf{p}_2$ the momenta of two particles, we form the vector of relative position and that of total momentum

$$\rho = \mathbf{r}_1 - \mathbf{r}_2, \quad \mathbf{P} = \mathbf{p}_1 + \mathbf{p}_2, \tag{1}$$

and determine their canonical conjugate variables' components of the vectors π and $\mathbf{R}$. A simple calculation shows that these are not uniquely determined but have the form

$$\pi = (1 - a)\,\mathbf{p}_1 - a\mathbf{p}_2, \quad \mathbf{R} = a\mathbf{r}_1 + (1 - a)\,\mathbf{r}_2, \tag{2}$$

where a is an arbitrary constant. Hence another condition must be added.

We postulate that the kinetic energy $p_1^2/2m_1 + p_2^2/2m_2$ assumes the form $P^2/2m + \pi^2/2\mu$. This condition leads to a determination of the three constants a, m, μ, namely,

$$a = \frac{m_1}{m_1 + m_2}, \quad m = m_1 + m_2, \quad \mu = \frac{m_1 m_2}{m_1 + m_2},$$

which introduced into (2) give the usual expressions for relative momentum and centre of mass.

In relativity, the energies E_1, E_2 of two free particles are given by

$$E_1^2 = m_1^2 + \mathrm{p}_1^2, \quad E_2^2 = \mathrm{m}_2^2 + \mathrm{p}_2^2. \tag{3}$$

We consider now the 4-vectors $\mathbf{p}_+ = \mathbf{p}_1 + \mathbf{p}_2$, $E_+ = E_1 + E_2$ and $\mathbf{p}_- = \mathbf{p}_1 - \mathbf{p}_2$, $E_- = E_1 - E_2$. A simple calculation leads to

$$E_+^2 = m_+^2 + p_+^2 + \pi^2, \quad E_-^2 = m_-^2 + p_-^2 - \pi^2; \tag{4}$$

here $m_+ = m_1 + m_2$, $m_- = m_1 - m_2$

and
$$\pi = 2m_1 m_2 \sinh \Gamma/2, \tag{5}$$

where Γ is the 'angular distance' of the two 4-vectors, given by

$$m_1 m_2 \cosh \Gamma = E_1 E_2 - \mathbf{p}_1\mathbf{p}_2. \tag{6}$$

Γ is invariant, hence π is invariant also. π has a simple meaning in the case of equal masses. In the rest system Σ°, where $\mathring{P} = \mathring{p}_+ = \mathring{p}_1 + \mathring{p}_2 = 0$, we have $m_1 - m_2 = m_- = 0$, and $\mathring{E}_1 - \mathring{E}_2 = \mathring{E}_- = 0$; hence $\pi^2 = (\mathring{p}_-)^2$. This shows that π is the length of the vector $\boldsymbol{\pi}$ representing relative momentum.

For different masses $\boldsymbol{\pi}$ can be described as the relative momentum in that Lorentz frame (which always exists) in which

$$E_1 - E_2 = \pm\,(m_1 - m_2).$$

The first equation (4) can now be written

$$E^2 = M^2 + P^2, \quad M^2 = \mu^2 + \pi^2, \tag{7}$$

where $\mu = m_1 + m_2$ is the sum of the rest masses, M the total internal energy, which represents also the rest mass of the whole system, and $\mathbf{P} = \mathbf{p}_+ = \mathbf{p}_1 + \mathbf{p}_2$ the total momentum.

Taking the components of $\mathbf{P}$ and $\boldsymbol{\pi}$ as new canonical momenta, one can determine the conjugate co-ordinates, $\mathbf{R}$ and ρ. They are linear in $\mathbf{r}_1$, $\mathbf{r}_2$; the coefficients are, however, not constants but functions of $\mathbf{p}_1$, $\mathbf{p}_2$.

For small $\mathbf{p}_1$, $\mathbf{p}_2$ the formulæ reduce to the classical ones.

It is interesting to remark that in relativity there exists a 'reciprocal'[2] theorem obtained by interchanging co-ordinates and momenta.

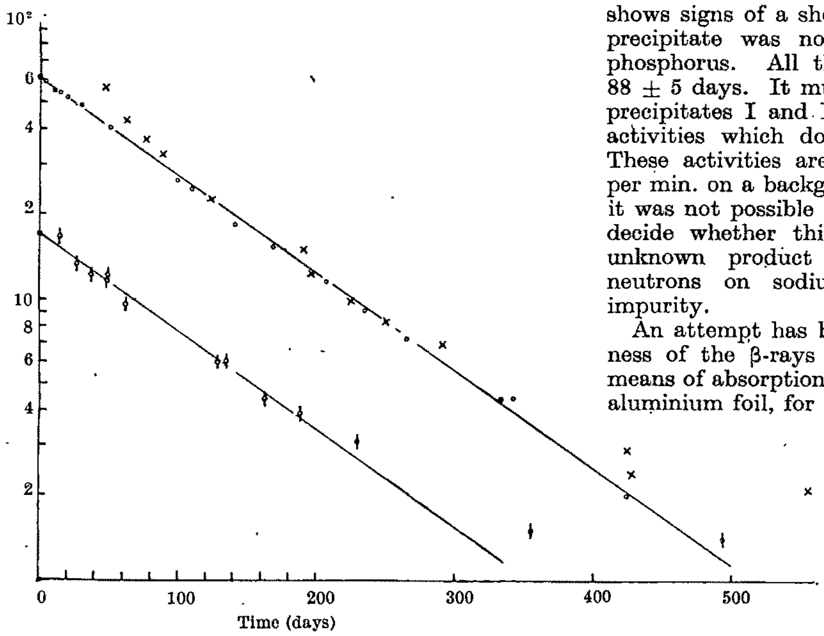
Radio-sulphur

A RADIOACTIVE isotope of sulphur produced by the action of neutrons on carbon tetrachloride and decaying with a period of 80 days was first observed by E. Buch-Andersen[1]. In view of the very weak activity found, doubt was expressed as to the existence of this isotope. This fact induced us to investigate the action of fast neutrons on carbon tetrachloride and sodium chloride. In both cases the radioactive sulphur was obtained; the use of sodium chloride was found, however, to be preferable. Recently[2], the $^{35}_{16}$S has been produced by the action of deuterons on sulphur, by making use of the Berkeley cyclotron.



DECAY CURVES FROM THREE BARIUM SULPHATE PRECIPITATES: ×, PRECIPITATE I; o, PRECIPITATE II; ϕ, PRECIPITATE III.

The neutron sources, consisting of 600 mgm. radium plus beryllium, were placed in the centre of a glass vessel containing 2 kgm. of pure sodium chloride. After the lapse of two months, the sodium chloride was dissolved in water, and 20 mgm. of inactive sodium sulphate was added. In order to oxidize the radioactive sulphur possibly present in elementary state, nitric acid and hydrogen peroxide were added, and the sodium kept boiling for several hours. 100 mgm. of sodium phosphate was added, and the phosphorus was precipitated as ammonium phosphomolybdate. This procedure was repeated several times until the precipitate showed no essential activity. Finally, the sulphur was precipitated in the usual way as barium sulphate.

The activity of barium sulphate precipitates was measured by means of a Geiger counter provided with an especially thin mica window with regard to the very soft β-radiation emitted from the $^{35}_{16}$S. The window was mounted on a concave cylindrical surface (radius 38 mm.) in order to make it possible to use an extremely thin mica foil as a window. It has been shown[3] that mica disks of 1·2 mgm./cm.^{2} and 1 cm. in diameter could stand evacuation of the counter only when mounted on such a concave surface. This mica window absorbs very little of the very soft β-radiation from sulphur.

The accompanying graph shows decay curves from three different barium sulphate precipitates obtained by the method described above; the decay was followed for more than 500 days. Precipitate I shows signs of a shorter period, indicating that this precipitate was not completely free from active phosphorus. All three curves show a half-life of 88 ± 5 days. It must, however, be mentioned that precipitates I and III seem to show weak residual activities which do not follow the 88-day decay. These activities are, however, so minute (1 count per min. on a background of 3 counts per min.) that it was not possible with the present arrangement to decide whether this weak activity is due to an unknown product obtained by the action of neutrons on sodium chloride or to traces of impurity.

An attempt has been made to estimate the hardness of the β-rays emitted by our preparation by means of absorption measurements. A 30 mgm./cm.^{2} aluminium foil, for example, reduced the activity to less than 10 per cent of its initial value. In the present arrangement, the β-rays from uranium were reduced to half their intensity by 125 mgm./cm.^{2} of aluminium. This enables us to estimate the upper limit of the β-rays from sulphur to be $1{\cdot}0$–$2{\cdot}0 \times 10^5$ ev., in agreement with Libby[4].

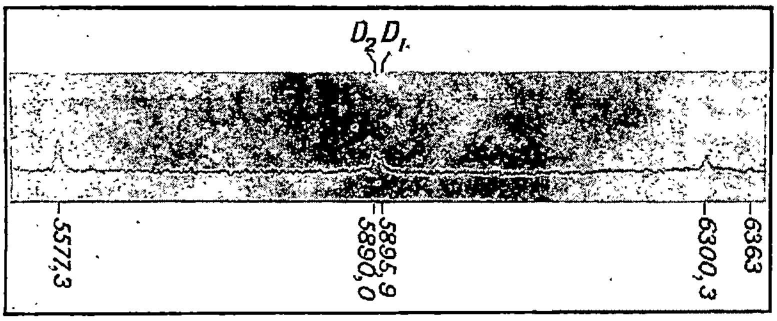
Origin of the Yellow Line in Twilight and the Night Sky Luminescence

THE appearance in the night sky spectrum of a yellow line was observed in 1929 by Slipher[1], who measured a wave-length 5892, by Dufay[2], Sommer[3], Cabannes[4] and by Vegard and Tönsberg[5]. The latter gave the wave-length 5892·6, and finding the line considerably broader than a single atomic line, they concluded that it had a fine structure. Twilight spectra giving the yellow line were obtained by Vegard at Oslo on January 13, 1936, and Tromsö in February of the same year[6].

Taking into account the time of exposure, the yellow line should be about 50–100 times stronger in twilight than in the night sky. In 1936 Currie and Edwards[7] published observations from the Polar Year programme showing the yellow line in twilight spectrograms. In November 1937 Bernard, working at the Tromsö Observatory, made further systematic investigations regarding the enhancement of the yellow line in the spectrum of twilight[8]. The wave-length found for the yellow line corresponds to the mean wave-length of the yellow doublet (D_1D_2) of sodium.



All the earlier wave-length measurements, which were based on spectrograms taken with very small dispersion (500–600 A./mm. at $\lambda = 5900$), were unreliable as a basis of interpretation.

An important step further was taken by Bernard[8], and at the same time and independently by Carbannes, Dufay and Gauzit[9], who analysed the fine structure with an interferometer and showed that the yellow twilight line had two components, the difference of wave-length of which was nearly equal to, or a single rational fraction of, that of the two components of the yellow sodium line.

These interferometer pictures, however, did not permit any wave-length determination, and until more accurate wave-length measurements were available, the origin of the yellow line could not be regarded as settled.

By means of a large glass spectrograph which at the yellow line has a dispersion of 99 A./mm., we obtained at Tromsö two spectrograms of twilight giving separation of the two components of the yellow line. The separation of the two components is shown in the accompanying reproduction of a microphotometer curve of one of the spectrograms, which also showed the green and red auroral O I-lines.

The D_1D_2 doublet of sodium was used as a comparison spectrum and *no difference between this doublet and that of twilight was observable in the comparator microscope. The two doublets also agreed with regard to relative intensity of the components.*

These results, together with the interferometer observations, show conclusively that the yellow twilight line is the D_1D_2 doublet of sodium.

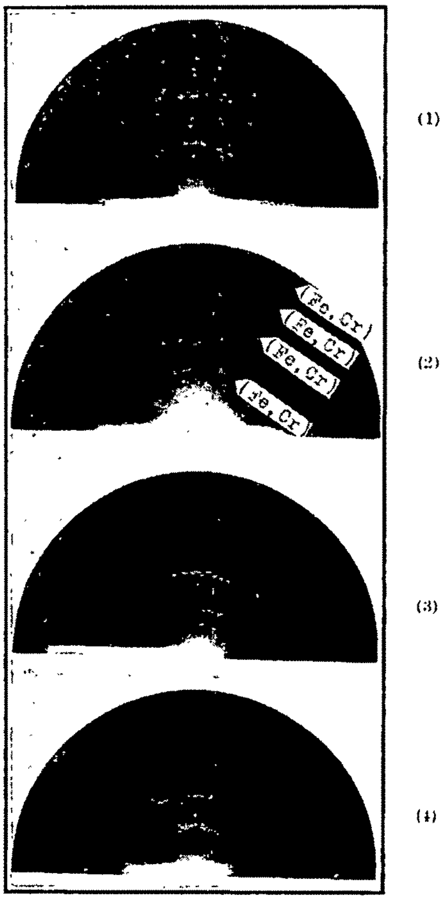
Oxide Film on Stainless Steels

Electron diffraction methods have been used by Miyake[1] in studying the oxide film on a stainless steel (17 per cent chromium) at high temperatures (600–900° C.), and the substance was thought by him to be $FeCr_2O_4$ co-existing with Cr_2O_3 or with a solid solution of Cr_2O_3 and α-Fe_2O_3. Also G. P. Thomson[2] in his work on some reflection experiments states that "the naturally occurring film on stainless steel is possibly $FeCr_2O_4$ (cubic : a = 8·1 A.)".

The entire range in the iron-chromium system has been covered in the present study of the surface of these alloys at different temperatures. An example of the pattern given by an iron-chromium solid solution is shown in Fig. 1, which was obtained from a surface of an alloy containing 26 per cent chromium. Fig. 2, which was taken from the above specimen after heating for 200 hours at 200° C., already shows a pattern revealing the existence and identity of an oxide. When heated to 600° C., the oxide became crystalline within an hour (Fig. 3), clearly proving to be the α-Fe_2O_3 type (hexagonal). This α-Fe_2O_3 type was obtained with alloys of the entire iron-chromium system when heated at temperatures lower than about 600° C., and the oxide is without doubt α-$(Fe,Cr)_2O_3$.

At higher temperatures, however, the form of the oxide obtained is entirely different. The pattern which is shown in Fig. 4 (1000° C. for 15 minutes) is similar to that of the Fe_3O_4 type (cubic) and is



(1) Pattern (Fe, 26% Cr), (as polished). (2) Oxide recognizable (200° C., 200 hr.). (3) Oxide developed, α-$(Fe, Cr)_2O_3$ (600° C., 1 hr.). (4) Oxide transformed, $FeCr_2O_4$ (1,000° C., 15 min.).

the same as the one Miyake identified with $FeCr_2O_4$.

In interpreting the experimental results summarized above, it is natural to consider the oxide formed at lower temperatures as the naturally occurring film, which in the case of stainless steels has now been shown to be α–$(Fe,Cr)_2O_3$.

I wish to express my thanks to Dr. Iitaka for his guidance and encouragement.

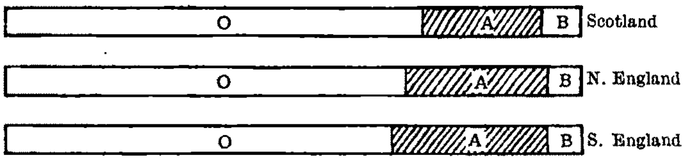
Scandinavian Influence in Scottish Ethnology

A FEW months ago[1] we appealed to centres of the emergency blood transfusion service, and in particular to those which we were supplying with testing serum, to allow us to assemble the extensive data on blood group frequencies in Great Britain, then for the first time becoming available. We were confident that such a collection would throw light on the precision with which such extensive groupings can be relied on to determine the gene-ratios in our population, and we hoped further that this precision might be sufficient to detect with certainty any such small variations of ethnographic significance as might exist within our island.

In a preliminary survey, exhibited at the meeting (January 12, 1940) of the Pathological Society at Cambridge, it was shown that a consistent gradient in the frequency of the antigen *A* is found as we pass from southern England to Scotland. Further data since accumulated bring our totals to 10,969 for Scotland and 8,716 for northern England, which show clearly intermediate frequencies. For southern England our compilation amounts to 106,477.



The values we present are not entirely unselected. A few returns have had to be set aside as apparently anomalous, and only in some cases has the cause of disturbance been ascertained. Systematic errors, not all of which are yet understood, do undoubtedly affect the frequency of the rarest of the four blood-groups (*AB*). As a further precaution, we have calculated the gene-ratios from the other three groups only, as in this way the effect of grouping errors is diminished.

The contrast between our three main areas, Scotland, England north of the Humber, and southern England, may be shown either in the relative frequencies of the four distinguishable phenotypes, or in those of the three allelomorphic genes :

TABLE 1

PHENOTYPIC FREQUENCIES

	O	*A*	*B*	*AB*
Scotland	52·019	34·233	10·429	3·318
N. England ..	48·600	40·340	8·536	2·524
S. England ..	45·232	43·162	8·508	3·097

The change in the ratio *A* : *O* is not, apparently, influenced by the traditional and political Border, but is apparently continuous, and doubtless a cause of heterogeneity, too slight to be detected on the numbers yet available, within the three chosen regions. The corresponding gene-frequencies are as follows :

TABLE 2

GENE FREQUENCIES

	O	*A*	*B*
Scotland ..	72·247	20·783	6·970
N. England ..	69·587	24·549	5·864
S. England ..	67·207	26·744	6·048

as shown in the diagram below.

It has been customary for ethnologists to suppose that the northern inhabitants of Britain differ from their southern neighbours by reason of a greater infiltration of Scandinavian blood. The modern Scandinavians, however, differ from the English in having not a lower but a higher frequency of *A*. Thus if, setting aside the small fraction of these populations carrying the gene *B*, we compare the phenotypic ratios $A/(A + O)$, we find, using the best available series, Norway 58·0, Sweden 58·6, Denmark 50·0, against S. England 48·8, N. England 45·4, Scotland 39·7.

English contact with neighbouring Europe has been extensive since the Roman period ; the values for Holland 48·6, Belgium 46·6, France 50·1, and Spain 53·4 are fully in accordance with the view that the English province has been influenced by settlement or intermixture with neighbouring Continental peoples. No Continental population, however, in the north or in the south, comes near to the Scottish ratio.

The only foreign sample we know of comparable to the new Scottish data is from Iceland. A sample of 800 in Wiener's collection gives the ratio $A/(A + O)$ as low as 36·6, slightly more extreme than the Scottish value. Now, Iceland was undoubtedly colonized from Norway, and, though men and women from Scotland and Ireland occur frequently in the Icelandic Sagas, it is not believed to have been extensively colonized from the British Isles. The stock from which the Icelanders sprang would seem to have just the blood-group constitution needed to harmonize with the gradient found in Great Britain, but in recognizing this stock as genuinely Scandinavian, we must distinguish it sharply from the modern Scandinavian peoples, which have evidently changed greatly, by infiltration from central or eastern Europe, since the Viking period. The Scottish and N. English blood-groups show, certainly not modern Scandinavian, but it may well be a proto-Scandinavian influence.

Kallikrein and Histamine

Kallikrein, Frey and Kraut's circulatory hormone, has been extensively studied from the pharmacological point of view by Frey, Kraut and Werle[1] and considered by Szakall[2] as the regulator of the capillaries and small vessels. This last condition would introduce some relationship between kallikrein and histamine. Recently, Ungar and Parrot[3] have shown that kallikrein produces secretion of gastric juice, and more recently Schneider and Springorum[4] have demonstrated the close similarity between the circulatory effects of kallikrein and histamine in the dog. All these facts have justified the inclusion of kallikrein among the histamine-like substances, although its physical and chemical properties exclude the idea of its being histamine itself.

To demonstrate the effects produced by kallikrein upon the small vessels of the rabbit skin we employed the trypan blue test. Kallikrein (= padutin) was injected intracutaneously in the adult rabbit and, five minutes after, a solution of trypan blue (1 per cent) was injected into the ear vein. A more and more extensive and beautiful blue spot appears in the locality of the intradermal injection. This positive reaction has been obtained by injection of irritant substances[5] and by a proper concentration of histamine[6]. Since the rabbit's skin is very rich in histamine, one might be induced to interpret this positive test as characteristic of a liberation of histamine. By assuming that kallikrein exerts its action by liberating histamine from the tissues, this would provide an explanation for its pharmacological properties.

Initially, a difficulty for this hypothesis would be the inactivity of kallikrein upon the isolated guinea pig gut. Moreover, we have verified that kallikrein inhibits the contracting action of histamine upon that organ; therefore, even if it liberated histamine from the smooth muscle, this last active substance would have its action inhibited by kallikrein itself. But in another way the hypothesis has been rendered very improbable by the fact that we have verified that kallikrein is also extremely active even upon the skin of very young rabbits (200 gm.), while histamine and a substance liberating histamine (turpentine) are not active or only very slightly so. Furthermore, in perfusion experiments with guinea pig lung kallikrein has been found devoid of any histamine liberating activity. Thus the pharmacological activity of kallikrein does not involve a liberation of histamine.

Indirect evidence has been put forward by Frey and Kraut[1] as well as by Szakall[2] for an increase of the capillary permeability after injection of large amounts of kallikrein. Since the seepage of the trypan blue into the intradermal injected area is very characteristic of an increase of capillary permeability, the experiment described above is a direct demonstration that kallikrein produces an abnormal filtration of colloidal matter through the walls of the capillaries.

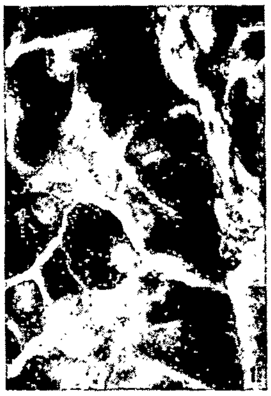
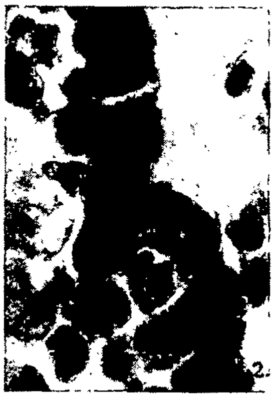
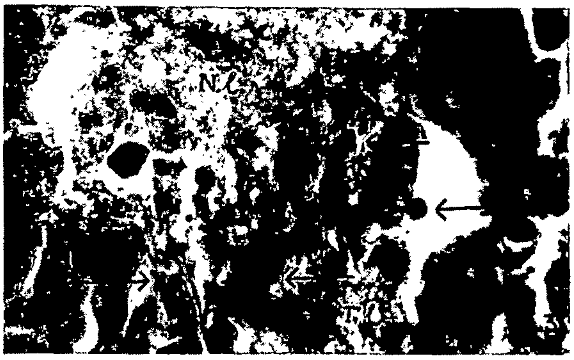
The Herring Material in the Perch Pituitary

In an investigation of the histology of the pituitary of the perch (*Perca fluviatilis*) a process of some general interest has come to light. Cells having the appearance of eosinophile leucocytes are present in the middle glandular or transitional lobe, and from them can be traced a succession of cells with fewer and larger inclusions to precise and brightly staining eosinophilic spheres which come ultimately to lie free among the cells of the lobe. In some series these spheres can be seen in all locations from the transitional to the nervous lobe, where they represent the larger elements of the Herring material in this form. Here in turn they appear to break down and form a characteristic granulation.







Photograph No. 1 (all photographs × about 1,000) shows two of these 'sphere cells' at an early stage among transitional lobe eosinophiles, No. 2 shows later stages, and No. 3 shows some spheres among the transitional lobe cells (*T. l*) and some in a process of the nervous lobe (*N. l*). No. 2 recalls certain cells noticed by Charipper[1] in the pituitary of Necturus, in which they appear to discharge directly into blood vessels. Herring[2] first described this material in the nervous lobe and looked upon it as probably secretion passing up to the third ventricle, but it has since been claimed to be simply unusual nerve endings in the lobe or an artefact due to precipitation. The sequence described here, however, including the demonstration of its origin, suggests that it is definitely secretory.

Inhibition of Respiration at Sub-optimum Substrate Concentrations

THE following note on respiration systems arose out of some calculations made for Mr. G. D. Greville in connexion with measurements of tissue respiration at the Middlesex Hospital, London. The case considered here is that with the substrate concentration less than the optimum and with carbon monoxide present as a respiratory inhibitor. The resulting equations are different from those originally obtained by Warburg[1], but, in correspondence, he has agreed with the present results.

We consider a homogeneous system respiring in a medium containing oxygen, carbon monoxide, and substrate.

In the absence of carbon monoxide, let A_s be the respiration with substrate concentration s, less than the optimum, and A the respiration with substrate concentration equal to or greater than the optimum.

In the presence of carbon monoxide, let A'_s and A' be the values corresponding to A_s and A. We now define

$$\varepsilon = A_s/A\,; \qquad \varepsilon' = A'_s/A'\,;$$
$$n_s = A'_s/A_s\,; \qquad n = A'/A\,;$$

so that

$$\varepsilon' n = \varepsilon n_s. \tag{1}$$

Let σ_{O_2}, σ_{CO}, and σ_s be those fractions of the catalyst which are combined with oxygen, carbon monoxide, and substrate respectively. When oxygen only is present, the respiration depends directly on σ_s, provided that the oxygen partial pressure is not less than a certain minimum value, which is always exceeded in practice, that is,

$$\sigma_s = \varepsilon. \tag{2}$$

When oxygen and carbon monoxide are present, residual respiration/inhibited respiration equals

$$n_s/(1 - n_s) = \sigma^s_{O_2}/\sigma^s_{CO}\,, \tag{3}$$

where $\sigma^s_{O_2}$ is that fraction of the whole catalyst which is in combination with oxygen and substrate simultaneously, and similarly for σ^s_{CO}. If the sum of the oxygen and carbon monoxide partial pressures is not less than a certain minimum value, then $\sigma_{O_2} + \sigma_{CO} = 1$, and this is the case in practice. We assume that the probability of finding an oxygen and a substrate molecule simultaneously in combination with a given catalyst molecule is equal to the product of the separate probabilities of finding oxygen or substrate molecules in combination with that same catalyst molecule, and similarly for carbon monoxide. That is, we assume that the distributions of both oxygen and carbon monoxide over the catalyst are independent of the distribution of substrate. Then

$$\sigma^s_{O_2} = \varepsilon\,\sigma_{O_2},$$

and similarly

$$\sigma^s_{CO} = \varepsilon\,\sigma_{CO}.$$

Therefore, from (3),

$$n_s/(1 - n_s) = \sigma_{O_2}/\sigma_{CO}. \tag{4}$$

Now, in the equilibrium state, rate of combination of oxygen with enzyme equals rate of dissociation of oxygen-enzyme complex plus rate of removal of oxygen by chemical reaction, that is,

$$\lambda_1 p_{O_2}(1 - \sigma_{O_2} - \sigma_{CO}) = \lambda_2\sigma_{O_2} + \lambda_3\sigma\,\sigma_{O_2}; \tag{5}$$

and similarly for carbon monoxide,

$$\mu_1 p_{CO}(1 - \sigma_{O_2} - \sigma_{CO}) = \mu_2\sigma_{CO}, \tag{6}$$

where p_{O_2} and p_{CO} are the pressures of oxygen and carbon monoxide in the solution, respectively, and λ_1, λ_2, λ_3, μ_1, μ_2 are constants.

Now, from equations (2), (4), (5), and (6), we have

$$\frac{n_s}{1 - n_s} = \frac{\sigma_{O_2}}{\sigma_{CO}} = \frac{p_{O_2}}{p_{CO}} \cdot \frac{a}{b + \varepsilon}. \tag{7}$$

where $a = \lambda_1\mu_2/\mu_1\lambda_3$ and $b = \lambda_2/\lambda_3$.

Also, from (1), we have

$$\frac{n_s}{1 - n_s} = \frac{\varepsilon' n}{\varepsilon - \varepsilon' n}. \tag{8}$$

It is evident from (7) that when the substrate concentration is diminished so that the system becomes unsaturated with respect to substrate, the respiration is less markedly depressed by carbon monoxide only when ε is not negligible in comparison with b. That is, when the rate of removal of oxygen by chemical reaction cannot be neglected in comparison with the rate of dissociation of oxygen-enzyme complex, or, in terms of the constants of the system, $\varepsilon\lambda_3$ is comparable in value with λ_2.

Publication of this result has been delayed many months because it was thought that an opportunity for verification might occur. As this has not been possible, the result is put forward in the hope that other workers in this field might be able to test it.

Photodynamic Hæmolysis by Carcinogenic Hydrocarbons

IN recent publications, Mottram and Doniach[1,2,3,4] reported that many carcinogenic hydrocarbons have a photodynamic effect upon Paramecia and upon the skin of mice. These hydrocarbons under the same experimental conditions did not cause photodynamic hæmolysis of erythrocytes.

This report deals with experiments made in order to find out whether by using a longer time of exposure, and a different technique of preparing the colloidal solutions of the three carcinogenic hydrocarbons, 3 : 4 benzpyrene, 1 : 2 : 5 : 6 dibenzanthracene, and methylcholanthrene, photodynamic hæmolysis could be obtained. (The carcinogens used were from the Union Chimique Belge 'Meurice'.)

The colloidal solutions of the hydrocarbons were prepared in the following way: 20 c.c. of isotonic saline solution were poured into a large Petri dish of approximately 30 cm. diameter. To this were added 10 c.c. of an acetone 1 : 10,000 hydrocarbon solution; the whole was left at room temperature, until all the acetone evaporated. The Petri dish was slightly shaken at the beginning in order to spread the solution all over the bottom. When the acetone had evaporated, the solution was poured into a test tube, care being taken to include all traces of hydrocarbon deposited on the wall of the Petri dish in the solution. This solution, which contains therefore a little less than 1 : 20,000 of hydrocarbon, was used throughout the experiment.

Red blood cells from sheep were washed three times in the ordinary way, and suspended in isotonic saline solution in the proportion of 1 : 100. The experiments were carried out in part by using a quartz mercury lamp (Hanau, type 'Jubiläums-Höhensonne', 220 volts, 3·8 amp.; distance 30–50 cm.), and in part in sunlight on bright days in February, March and April in Jerusalem. All the experiments were conducted in simple glass test tubes, of 8–9 mm. diameter.

Preliminary experiments in the dark, temperature measurements, and contemporaneous irradiation of control test tubes containing the suspension of red blood cells without the hydrocarbon, have eliminated the possibility of errors.

The results of our experiments may be summarized as follows:

(1) The colloidal solutions of 3 : 4 benzpyrene, 1 : 2 : 5 : 6 dibenzanthracene, and methylcholanthrene produced photodynamic hæmolysis.

(2) Under conditions in which we worked, in sunlight and with the above-mentioned dilution, the time required for complete hæmolysis was 1–1½ hours for 3 : 4 benzpyrene, 2½–3½ hours for 1 : 2 : 5 : 6 dibenzanthracene, and 1½–2 hours for methylcholanthrene.

(3) With the mercury-vapour lamp, the time required for complete hæmolysis for 3 : 4 benzpyrene and methylcholanthrene was 3 hours; with 1 : 2 : 5 : 6 dibenzanthracene hæmolysis was not complete after 4½ hours. The time required to obtain this hæmolysis by the hydrocarbons is much longer than the time required for them to produce a photodynamic lethal effect upon Paramecia—a fact which might have been foreseen from the results obtained by Mottram and Doniach. While Paramecia suspended in a 1 : 20,000 solution of 3 : 4 benzpyrene and irradiated by the quartz lamp under the above-mentioned conditions were killed in 5–7 minutes, the time required for complete hæmolysis under the same conditions was 3 hours.

Further studies which it is hoped will make it clear whether similar but non-carcinogenic hydrocarbons also possess photodynamic activity are being pursued. As yet, of four non-carcinogenic hydrocarbons tried, 1 : 4 diphenylanthracene, 9 : 10 diphenylanthracene, 1 : 4 : 9 : 10 tetraphenylanthracene and chrysene, not one has shown any photodynamic activity. (The non-carcinogenic hydrocarbons were kindly supplied to me by Dr. E. Bergmann, of the Daniel Sieff Research Institute, Rehovoth.)

Points from Foregoing Letters

M. Born presents a relativistic formulation of the theorem of the mass centre for free particles.

The radio isotope of sulphur, $^{35}_{16}$S, has been prepared by Hilde Levi from sodium chloride and from carbon tetrachloride. The sodium salt, which was found preferable for this purpose, was exposed for two months to neutrons from radium plus beryllium. Sulphur was precipitated as barium sulphate and was found to have a half-life of 88 days.

Using a large glass spectrograph of high dispersion, E. Tönsberg and L. Vegard have obtained spectrograms of twilight in which the two components of the yellow line are separated. This doublet appears, from the microphotometer curve, to be identical with the sodium doublet (D_1D_2).

T. Tokumitu finds that the two kinds of oxides formed on stainless steels are α–(Fe,Cr)$_2$O$_3$ at low temperatures and FeCr$_2$O$_4$ at high temperatures. His experimental results suggest that the naturally occurring film is the α–(Fe,Cr)$_2$O$_3$ form.

R. A. Fisher and G. L. Taylor state that new blood grouping data for England and Scotland show a decided gradient in the ratio $A : O$, antigen A being rarer in Scotland. This is the reverse of the effect of admixture with modern Scandinavians, who have more A than the English. Data from Iceland suggest, however, that Scandinavians of the Viking period conformed with the Scottish, and not with the modern Scandinavian, ratio.

M. Rocha e Silva presents strong evidence for an increase of the capillary permeability produced by kallikrein. The intradermal injection of kallikrein in the rabbit determines a seepage of trypan blue injected into the vein.

T. Kerr describes the origin of the Herring material in the perch pituitary from cells resembling eosinophile leucocytes found in the so-called transitional lobe. The granules of these cells become fewer and larger to form globules of various sizes which are set free in the tissue and find their way into the nervous lobe to form the larger elements of the Herring material. Here in turn they break down to become a fine granulation.

Warburg's treatment of the inhibition of respiration by carbon monoxide at sub-optimum substrate concentrations is incorrect. W. F. Floyd puts forward a solution to the problem with which Warburg has agreed in correspondence, but which has not yet been tested experimentally. The proposed solution shows that the inhibition of respiration is markedly diminished by unsaturation with respect to substrate only when the rate of utilization of oxygen is not negligible in comparison with the rate of dissociation of oxygen-enzyme complex.

M. Wolman has obtained photodynamic hæmolysis by the three carcinogenic hydrocarbons, 3 : 4 benzpyrene, 1 : 2 : 5 : 6 dibenzanthracene, and methylcholanthrene. The four non-carcinogenic hydrocarbons, 1 : 4 diphenylanthracene, 9 : 10 diphenylanthracene, 1 : 4 : 9 : 10 tetraphenylanthracene and chrysene, did not produce any such effect.

RESEARCH ITEMS

Early Mayan Datings

A NEW series of publications of the National Geographic Society at Washington, D.C., is inaugurated by a study by M. W. Stirling, chief of the Bureau of American Ethnology, Smithsonian Institution, of a Mayan dating carved on a broken and re-used stela from Vera Cruz, Mexico ("An Initial Series from Tres Zapotes, Vera Cruz, Mexico", *Nat. Geog. Soc.: Contributed Technical Papers, Mexican Archæology Series*, 1, 1; 1940). This monument was discovered in the course of archæological explorations conducted by a joint expedition of the National Geographic Society and the Smithsonian Institution at Tres Zapotes, Tuxtlas, Vera Cruz. Of some fifty mounds in four groups, each group with a rectangular plaza as a central feature, the easternmost, *C*, includes the second largest mound of the entire series, *C*1. In front of its south base was found a stela set up behind a roughly circular flat stone altar. It was a transverse fragment, intentionally broken in the middle, of a monument carved by an earlier people than those who re-used it. Facing the altar was a 'tiger-face' mask panel in low relief, while across the middle of the back was the greater part of an initial series. The numerals are in a vertical column with bars and dots placed horizontally—a rare but not unknown arrangement. The inscription is imperfect, but as restored by fully supported argument, it affords a dating which coincides with pottery finds, not yet fully worked out, but apparently to be assigned to the Middle American ceramic horizons. Only four other Initial Series are known, in which the style, with the horizontal arrangement of dot and bar, resembles that of this stela *C*, which is also the earliest of a group representing the earliest dates known in the entire body of Mayan inscriptions, and the three earliest of which have been found outside the classic Maya region.

Technique in Prehistoric Trephining

T. WILSON PARRY describes in *Man* of March 1940 the presumable method employed in trephining two prehistoric British skulls. Of these, one was found at Maiden Castle, Dorchester, in 1937 in association with a neolithic beaker of type *B*, the second in 1938 by Stuart Piggott in an early bronze age burial on Crichel Down, Dorset. At the time these two operations were performed, a notable advance in technique had been made, since the removal of a roundel of bone was more difficult and arduous than the elimination of a piece of bone reduced to dust by scraping, the method followed hitherto. In both examples the roundel had been removed from the left parietal. The dimensions in the Maiden Castle (late neolithic) skull operation are: laterally 65 mm.; ant. post., 52 mm.; oblique bevel of bone, 5–8 mm.; vert. thickness of skull, 5–7 mm. The corresponding dimensions in the Crichel Down (early bronze) skull are: laterally 60 mm.; ant. post., 70 mm.; oblique bevel surface, 9–14 mm.; vertical thickness of skull, 5–14 mm. The Crichel Down skull is altogether thicker and heavier than that from Maiden Castle. A specimen from the Grotto of Casa da Moura at Peniche, Portugal, now in the Geological Section of the Lisbon Museum, showing a continuous curving furrow united at both ends, is regarded as the first stage of the removal of a roundel of bone, the operation being unfinished. This method has not hitherto been described, but experiment with a neolithic beaked implement of flint on a recent skull has demonstrated the efficacy of what is here termed "the push plough" method, in which a thin, shallow furrow is gradually deepened until the bone is perforated. In neither skull is there any reparation of bone, so that if the operation was performed on the living, neither recovered.

Epidemic Dropsy in India

THE annual report for 1938 of the All-India Institute of Hygiene and Public Health, Calcutta, summarizes the teaching and research work carried out during the year. A most interesting research has been conducted on the disease known as 'epidemic dropsy'. A critical survey of its epidemiology, with much experimental work, led to the conclusion that this disease is associated with the use of mustard oil containing some toxic constituent. Mustard oil is widely used by the inhabitants for culinary purposes, and it was found that while some samples of mustard oil are innocuous, others are associated with the occurrence of epidemic dropsy, and experimentally induce the lesions associated with the disease. Investigation showed that the non-toxic and toxic oils could be distinguished by certain chemical and physical tests. Further investigation suggested that the toxic mustard oils might derive their toxic properties from some poisonous seed resembling mustard seed and mixed with it. After examination of a number of specimens of mustard seed, the seeds of *Argemone mexicana* were suspected to be the source of the poisonous substance in mustard oil. This plant grows wild and plentifully in various parts of India and becomes mixed with the mustard seeds at the time of harvesting. It was found that a mixture of 6 per cent of the oil expressed from the Argemone seeds with non-toxic mustard oil satisfied the same chemical and other tests as the known toxic oil, and experimentally induced the same lesions as the latter. The nature of the toxic agent is still under investigation.

Carotenoids and the Metabolism of Reproduction

THE possibility that carotenoid pigments have important biochemical roles in sexuality and the processes involved in the metabolism of reproduction is emphasized by R. Emerson and D. L. Fox (*Proc. Roy. Soc.*, B, **128**, 275; 1940). In the life-cycle of certain species of the aquatic phycomycete Allomyces, an asexual or sporophytic generation bearing thin-walled, colourless zoosporangia and thick-walled, brown, resistant sporangia, alternates with a sexual or gametophytic generation bearing colourless female gametangia and orange male gametangia. The pigment in the brown resistant sporangia of the asexual phase belongs to the melanin class and contains no carotenoid material. The orange pigment found exclusively in the male cells of the sexual phase is present in oil droplets within the cytoplasm and is not found in the walls of the male gametangia, but is still apparent in the male gametes after their emergence from the gametangia. The female gametes, which are more than twice the size of the males, contain no trace of pigment. In the orange pigment of the male cells, γ-carotene was found in high concentrations with variable small amounts of β-carotene. The authors point out the accordance of these findings with the existing knowledge of the synthesis and selective storage of carotenoids or their derivatives in structures associated with reproduction in many cryptogams, higher plants and animals.

Induction of Polyploidy in Rabbit Ova

G. Pincus and C. H. Waddington (*J. Hered.*, 30, 515–518 ; 1940) have treated fertilized ova of rabbits *in vitro*, with ethyl alcohol, ether, colchicine or with supra-normal temperatures. These treatments gave a significant decrease in the cleavage rate, while cytological examination showed that fifteen out of forty eggs were tetraploid, most of the tetraploids being in the colchicine series. It is suggested that the inhibition of cleavage and the rate of chromosome division are differently affected so that sometimes tetraploid ova are formed. Tetraploid ova ordinarily fail to cleave, but the few that do cleave do so at a subnormal rate.

Interspecific Hybridization in Medicago Hybrids

THE diploid form of *M. falcata* ($2n = 16$) does not readily cross with *M. sativa* ($2n = 32$), but the more usual hybrids are between the tetraploid *M. falcata* and *M. sativa*. The resulting hybrids form a fertile polymorphic group. Analysis of these hybrids and of artificial hybrids made between diploid *M. falcata* and *M. sativa* are described by G. F. Ledingham (*Genetics*, 25, 1–15 ; 1940). A histological examination shows that in the cross *M. falcata* ♀ × *M. sativa* ♂, fertilization takes place and development continues for about a fortnight. In the reciprocal cross, fertilization occurs, but development usually ceases after two days. It is suggested that the rate of physiological activity and cell division of the endosperm embryo and maternal tissue is initiated by the chromosomes of the gametic nuclei.

Fruit Flies of Northern China

IN *Sinensia*, 9 (1938), Nos. 1–2, pp. 1–150, there is an extensive contribution on the Trypetidæ or fruit flies of North China by Y. Zia and Sicien H. Chen. The journal in question, it may be added, is issued by the National Institute of Zoology and Botany, Academica Sinica, Pehpeichang, China. The present study is based upon material collected during a period of twenty-five years. Altogether, thirty-six genera and one hundred and thirty-five species are dealt with in this monograph. It is noteworthy that two of the genera and sixty-two of the species are described as being new. Special mention is made of the occurrence of two species of the genus Rhagoletis, namely, *R. reducta* and *R. scutellata*, for the reason that members of this genus are well known to cause much damage to fruits in Europe and North America. Although the relation of the two species named to horticulture in North China is unknown, their presence is noteworthy and is regarded as a menace to fruit production. It is creditable that, notwithstanding the disturbed condition of affairs in so much of China, the progress of natural science has not been wholly dislocated.

Sand-Dwelling Copepods

A. G. NICHOLLS continues his studies on copepods living in sand (*J. Marine Biol. Assoc.*, 23 ; 1939). New species are described from the Firth of Clyde and also from the St. Lawrence River. Revised keys are given for the species of Leptopsyllus and Paramesochra, Leptopsyllus now being restricted to those forms which lack endopods on the second legs. The two genera have been for some time in a state of considerable confusion, and although the author follows Kunz (1938) in basing the distinction on the presence or absence of an endopod on the second leg, he is of the opinion that the separation is not a natural one but will suffice until a thorough revision of these and allied genera has been made. An interesting find from Fintray Bay, Isle of Cumbræ, is *Remanea arenicola* Klie, occurring in relatively coarse sand near low-water mark. This species is so far only known from Kiel Bay. Three new species of Leptopsyllus and four of Paramesochra are described.

Weather and Radial Growth of Trees

AT the recent meeting of the American Association, Charles J. Lyon reported data from a New England forest, where suitable trees in close proximity to a meteorological station were blown down in a hurricane in 1938, as the result of an examination of their radial increment in comparison with the meteorological records. White pine, Scotch pine and red oak showed significant correlation with the rainfall of the spring months; but Austrian pine, Norway spruce and European larch showed no consistent correlation with the precipitation records of any period. There was almost no agreement between growth-rates and temperatures, though all the coniferous trees gave significant correlations between growth-rate and the temperatures of March and April, *before* the growth starts. This is interpreted as an effect of water supply, since the temperature of the air determines the frost in the soil. When the frost remains late in the spring, the water from the melting snow and from the early spring rains runs off to the rivers ; but this water is added to the water supply of the trees if the frost leaves the soil early. On the whole, the native white pine tree is particularly sensitive to its water supply, and was the best indicator tree of those tested in this study. The width of its annual rings is a better index of growing conditions for crops and forests than the weather bureau records of rainfall and temperature for the year.

Water Culture of Apple Trees

TREES of many different species have from time to time been grown in nutrient solutions, and the method has been widely used in nutritional studies. H. L. Pearce (*J. Pom. and Hort. Sci.*, 17, 344 ; 1940) has recently used the method for comparing the course of absorption of nitrogen and potassium in dwarf and vigorous apple trees. One year old trees of Cox's Orange Pippin on Malling stocks IX and XII were grown in continuously aerated culture solutions for a complete season and the absorption of nutrients and water followed by analysis of the external solution. Growth records showed that the two rootstocks maintained their respective dwarfing and vigorous habits in these conditions, whilst the uniformity of the trees was greater than that obtained in soil. An unusual feature was the fact that the trees on *M* XII, which normally exhibit delayed blossoming compared to trees on *M* IX, bore blossom as freely as those on the dwarfing rootstock. The vigorous trees absorbed more water per unit leaf area throughout the season than the dwarf trees, though the latter absorbed more per unit increase in fresh weight. The course of nitrogen and potassium uptake was closely similar in the two kinds of tree. The absolute amounts absorbed were greater for the tree on *M* XII, but the ratios of total growth made to nutrients absorbed did not differ significantly. No relation could, therefore, be observed between nutrient absorption and vigour.

Soil Decomposition of Straw

A RECENT paper by T. S. Sadasivan (*Ann. Appl. Biol.*, 26, No. 3, 497–508 ; 1939) shows that wheat straw is decomposed in soil largely by the activities of *Fusarium culmorum* and Mucor spp. These fungi were found on six different soils, but they appeared to give place to Penicillium spp. in the later stages of decay, or when the straw was treated with sodium nitrate.

Geochemistry of Fluorine

THERE has been little information available about the amounts of fluorine present in rocks, the lack of data being due mainly to the difficulty, hitherto, of determining fluorine with accuracy. The Willard and Winter procedure (*Ind. Eng. Chem.*, 5, 7–10 ; 1933) now furnishes an easy and surprisingly accurate method of analysis. E. S. Shepherd has established (*Amer. J. Sci.*, 117, 128 ; 1940) that fluorine is not so insignificant a constituent of the earth's crust as had been supposed. It is evidently present in quantities as great as, and sometimes greater than, chlorine, and this raises a question to which there is at present no satisfactory answer. What becomes of all this fluorine on denudation ? The author hopes with continued work to be able to trace the vagaries of this elusive element. Meanwhile, it appears that plutonic rocks characteristically contain about 0·04 per cent. The lavas examined tend to have about 0·01, even where large amounts of fluorine are known to have been exhaled. Obsidian, however, has an average content of 0·07, rising exceptionally to twice this amount. In certain regions, notably the African rifts, there are strong local concentrations. In sedimentary rocks the average is 0·027, but ocean bottom samples have nearly twice as much. No correlation between fluorine and other elements has yet been detected, except a dubious one with potassium. A suggested relationship with phosphorus has not been confirmed.

Molecular Rotation in Organic Crystals

DIELECTRIC constant measurements have established the rotation of molecules in certain crystals, such as those of halogen hydracids and hydrogen sulphide, and also in some organic compounds, including certain polar derivatives of camphane, cyclohexane and ethane. A. H. White, W. S. Bishop, B. S. Biggs and S. O. Morgan (*J. Amer. Chem. Soc.*, 62, 8, 16 ; 1940) have extended this field by dielectric constant measurements with crystals of two derivatives of ethane, one of cyclopentane, five of cyclohexane, and thirteen of camphane in the non-aromatic class, and with a number of benzene derivatives (3,4,5-trichloro-*o*-xylene, trichloro-*m*-xylene, 3-nitro-4,5-dichloro-*o*-xylene, 5-nitro-3,4-dichloro-*o*-xylene, pentachloroethylbenzene, pentaethylacetophenone, pentamethylnitrobenzene and *o*-dinitrotetramethylbenzene). In the case of the non-aromatic compounds, the dielectric constant mostly rises abruptly at a transition to a value characteristic of polar liquids, as the temperature is increased. A relatively symmetrical gravimetric and volumetric distribution of atoms around the centre of gravity of the molecule facilitates its rotation in the crystal. In the aromatic compounds the dielectric constant of the solid behaves like that of the corresponding liquid and may be correlated with the dipole moment. The less symmetrical of the molecules cease rotating abruptly at transitions, while the more symmetrical exhibit reduced frequency of rotation but no transitions with falling temperature. The temperature at which the relaxation time reaches a given value depends (with one exception) on the number of chlorine atoms in the molecule in the symmetrical hexasubstituted methylchlorobenzenes.

Magnetic Spectrograph Coils

WHEN a beam of slow-speed electrons or ions is to be analysed by projecting it through a magnetic field, it is advisable to make the field in the vicinity of the trajectory as uniform as possible, and in many cases two equal coils placed coaxially at a distance apart equal to their radii have been used. With the same electric current in the same direction through the coils, the field in the median plane is uniform near the magnetic axis only. M. Ference, A. E. Shaw and R. J. Stephenson, of the University of Chicago, have shown (*Rev. Sci. Inst.*, February 1940) that it may be rendered uniform over the volume of a ring of radius up to a third of that of the coils by bringing the coils a little closer together. The theoretical proof of this is verified experimentally by balancing the field against that of a standard coil, using a small magnet and mirror to test the balance. With coils of 30·776 cm. radius, the field within a ring of mean radius 8 cm. is most uniform with the coils 28·890 cm. apart, and within a ring of 10 cm. with them 27·838 cm. apart. In the latter case the change of field from 9 to 11 cm., and from the median plane to parallel planes 1 cm. away, is only one part in 4,000.

Nebulæ and Star Clusters in the Southern Hemisphere

H. Shapley and J. S. Paraskevopoulos have given some interesting pictorial results of a study of thirty nebulæ and clusters photographed with the 60-inch reflector at the Boyden Station, Bloemfontein, of the Harvard College Observatory (*Proc. Nat. Acad. Sci.*, January 1940). Three quarters of the external galaxies (extra-galactic nebulæ) that are near enough for close classification are spiral in structure, and most of the spirals can be placed in a few common categories. The illustrations given include several instructive curiosities and abnormal forms. One of these shown is *NGC* 55 (exposure 2 hours), which with a major axis of nearly 33′ is probably exceeded in angular dimensions only by the Andromeda Nebula and Messier 33. Its linear dimensions may prove to be outstanding among the external galactic systems. South African plates for the detection of Cepheid variable stars, used as distance indicators, are accumulating. Another plate shows the well-known globular cluster, Omega Centauri (exposure time 1 hour), one of the most remarkable of star clusters. Its total absolute magnitude is comparable to that of the small external galaxies, such as the companions to the Andromeda Nebula.

SUGGESTIONS FOR NEW UNITS IN PHYSICS AND ENGINEERING

A COMMUNICATION received from the Bureau International des Poids et Mesures summarizes the conclusions reached at the meetings last summer of the Consultative Committees for Electricity, Photometry and Thermometry. These conclusions would, in the normal course, have been reported to the International Committee for Weights and Measures at its meetings which were to have been held last September.

The Consultative Committee for Electricity recorded three resolutions. The first contains a recommendation as to the relationships which should be accepted between the existing international units and the proposed new practical absolute units, namely:

1 mean international ohm = 1·000 5 ohm (abs.)
1 ,, ,, ampere = 0·999 9 amp. (abs.)
1 ,, ,, volt = 1·000 4 volt (abs.)

The second resolution contains a number of clauses defining the proposed new units and the procedure to be followed in establishing and maintaining suitable reference standards. The third relates simply to the desirability, in order to avoid confusion, of appending the qualification "international" (abbreviated to "int.") or "absolu" (abbreviated to "abs.") in all references to the two series of units during the period of transition.

The Consultative Committee for Photometry also passed three resolutions. The first of these suggested that, while the 'new candle' should be introduced in legislation as from January 1, 1940, its legal application should be deferred until January 1, 1941. The second records a recommendation that comparisons of lamps at the higher colour temperature of 2800° K. should be organized forthwith between the various national laboratories; and the third outlines the relationship between the old and new units and the procedure to be adopted for the establishment of the new standards necessary.

The Consultative Committee for Thermometry passed two resolutions. The first of these records that, in the opinion of the Committee, the most probable value of the melting point of ice on the Kelvin scale, according to experiments so far completed, should be taken as 273·15° ± 0·02°. The second recommends that the unit of 'heat' should be the quantity of heat equivalent to the 'Joule', or 10^7 ergs; that the calorie should be defined as 3600/860 joules, or 1/860 watt-hours; and that the terms kilogram-calorie, or 'large' calorie, should in future be replaced by "kilo-calorie"; these recommendations to be submitted for approval, before final adoption, to the International Union of Physics, the Commission of Physico-Chemical Constants, and the Steam Tables Conference. In addition, the Committee recommended certain minor modifications to the existing specifications of the International Temperature Scale.

It will be realized that the functions of the Consultative Committees are purely advisory, and that any decisions based thereon must be taken by the International Committee itself. The fact that, as a result of the War, this Committee was unable to meet as arranged, has left all these various resolutions unconfirmed. In particular, some uncertainty arises as to the precise position with regard to the introduction of the proposed new electric and photometric units, which the International Committee had previously decided should come into force on January 1, 1940. The Consultative Committees concerned both encountered difficulty with regard to implementing these previous decisions.

In a covering letter to the summary, the acting president and secretary of the International Committee suggest that in all the circumstances, since uniformity of international action is most desirable in such matters, the introduction of the new units should be deferred until such time as the Committee is able to issue a further pronouncement.

TYPE TESTS IN ENGINEERING

IN a paper in the *Beama Journal* of January W. A. Coates, c/o Metropolitan-Vickers Electrical Co., Ltd., discusses the significance and value of type tests in engineering. A type test is defined as a text made on one piece of material or apparatus, which is accepted as indicating the characteristics of another. Naturally, therefore, there is always an element of chance when interpreting and applying the results of such tests.

One of the oldest examples of a type test is to be found in the practice of making castings with projecting portions, which are eventually cut or sawn off and tested for mechanical, physical or chemical characteristics or for two or three of them. It is probable that the data obtained in this way apply also to the casting; the latter, however, would be destroyed in similar tests. The value of tests on samples depends on the skill with which the pieces were located and if the metal were poured so as to ensure a uniform cooling rate with the main body of the casting. More trustworthy data are obtained by testing metal cut from the main body of the casting. In important parts this is often done by trepanning out a piece where a hole is required. The closer that such samples are taken from the metal which will be used, the nearer is the test to a true test.

In electrical work, analogous type tests can be found in Brit. Spec. 137 (1930), which deals with porcelain line insulators. In these tests for ascertaining the puncture and porosity figures, the insulator is destroyed in the process. The mechanical, electro-mechanical and temperature-cycle tests are carried out on a proportion only to save time and expense. Mechanical tests must, from their nature, be made on insulators one at a time, while temperature cycle tests cannot be made in less than six hours, and are very awkward to carry out with more than a few units at a time.

Skilled craftsmanship plays a greater part in porcelain manufacture, both in the moulding and the firing, than it does in the production of rolled or drawn metal. This is reflected in the incidence of tests. A simple set of tests would usually satisfy a purchaser of several tons of rolled steel, but of the insulators 0·5 per cent is the minimum standard quantity tested. If in these a failure is recorded, a second batch of 1 per cent is tested. A failure on the second group of tests is followed by tests on 1·5 per cent, and if there are defects among these, the whole quantity is rejected. The increasing size of the batch tested is a clear indication of increasing suspicion about the quality of the bulk. In more readily controlled materials it is not usual to increase the percentages tested, even if failure does occur in the initial batch.

Electrical work presents also another class of type-tests such as in those made to determine the impulse voltage characteristics of an insulator or bushing. The impulse ratio depends almost completely upon the physical dimensions and the relative dispositions of dielectrics and conductors in such apparatus. Without changing these features, there is practically nothing that can be done in course of manufacture which would sensibly alter the impulse breakdown values. Thus a type-test on any one of a batch of dimensionally similar units is adequate to prove the characteristics of all. It is, in fact, a purely design test.

The tests carried out by the Home Office Mines Departments at Buxton, to prove electrical apparatus safe for use in explosive atmospheres, are also in this group. Inspection which shows identity of detail conveys full confidence that duplicates of the tested apparatus are equally flameproof.

Recently, the industry has become increasingly aware of a new group of type-tests, namely, those made on circuit breakers, which are covered by certificates issued by the Association of Short-Circuit Testing Authorities or the National Physical Laboratory. These two bodies are now working in conjunction to carry out and certify the short-circuit type-tests made in conformity with the requirements of Brit. Spec. 116 (1937). This standard specification calls for other tests also, but these are of a well-understood nature and may be made with apparatus found in any properly equipped factory.

The over-voltage tests on insulation and those made to check the operation of tripping and closing coils, are carried out on every breaker as a matter of routine. Hydraulic tests to prove tank strength and adequacy of joints need not necessarily be made on every breaker. This also applies to the mechanical endurance test, which consists of opening and closing the breaker 500 times on no-load. A test of this kind is necessary on any complicated mechanism, to ensure that some trifle, which might cause ultimate failure by excessive wear or distortion in service, has not been overlooked in design.

The practical circumstances in which a breaker may have to perform vary widely, and the accompanying electrical and physical phenomena are very complex. It is impossible, therefore, to separate the short-circuit tests into a series, each of which is simple and clearly defined, as can be done, for example, with an insulator. The only possible method of carrying out these tests is to use a testing generator which has short-circuit characteristics like those of the largest power stations. The operation, control, and recording work with such call for technical skill of an uncommon and very high order. The type-tests that have been devised are of an all-embracing character, and represent the worst that could happen in service; they are far more severe than is likely to occur in the majority of cases. It is essential to do this, because the primary duty of the breaker is to protect all other connected apparatus.

It will be generally agreed that the proper fields for type-testing are: (*a*) whenever the process of testing must destroy the article; (*b*) whenever the test is to determine a characteristic which is dependent upon dimensions and physical positions of parts; and (*c*) whenever individual testing would increase the cost of the finished article to an uneconomic level.

DUGGAN-CRONIN BANTU GALLERY, KIMBERLEY

WHEN in 1929 the British Association visited South Africa, the anthropologists in particular were much impressed by the scientific value, as well as by the importance as a record, of the collection of photographs of characteristic types of the native races of South Africa, which had been formed and was still being augmented by Mr. A. M. Duggan-Cronin. This impression was fully confirmed by further examination of the material placed on exhibition by Mr. Duggan-Cronin at the centenary meeting of the Association held in London in 1931.

Mr. Duggan-Cronin's interest in native types was first aroused when, as an employee of the De Beers Company in Kimberley, he was brought into contact with the wide variety of tribesmen who sought employment in the mines. After mastering the technique, he began his photographic series of racial types in 1904; but it was not until 1919 that he was able to undertake work in the field, when at the instance of the Board of the McGregor Institute, Kimberley, he visited the Langenbergen, Griqualand West, to photograph the Bushmen living there. Since that time, each year Mr. Duggan-Cronin, with the financial assistance of the Union Research Grant Board or from the Carnegie funds, has carried on his work, visiting one or other of the South African peoples, until a record has been made of every important Bantu tribe in the Union and of a number elsewhere, as well as of the Yellow races, Bushmen and Korannas. These records, to the number of 2,600, have been mounted in albums and the negatives stored in a strong room of De Beers. The material has also been published in part in eight volumes with the Cambridge University Press, while seven further volumes await publication.

From 1925 onward Mr. Duggan-Cronin, in view of the fact that no Bantu gallery existed in South Africa, threw his collection open to the public, maintaining the gallery at his own expense. After twelve years, however, it was offered as a gift to the town of Kimberley, subject to the provision of suitable housing. The gift was accepted and the collection was officially declared open in 1938 as the Duggan-Cronin Bantu Gallery by Sir Ernest Oppenheimer, chairman of De Beers Company, in premises, formerly the guest house, generously provided by that company, together with £150 per annum towards the cost of upkeep.

The unique character of many of these photographs as records from the cultural, as well as the racial point of view, was the subject of commendatory reference at an exhibition which was held at a recent joint meeting of the Rhodesia Scientific Association with the newly formed Rhodesia Photographic Society at Salisbury (*Transactions*, 37 ; 1939), when attention was directed to, among others, the complete series illustrating the smelting of iron ore among the Mashona, and the initiation ceremony of the Bomvana Kwetas. In the Bantu Gallery at Kimberley the photographs are supplemented and further illustrated by objects of the tribal culture collected by Mr. Duggan-Cronin.

THE EARTH'S INTERIOR

K. E. BULLEN has examined the recent developments in knowledge of the earth's interior (*Acta Astronomica*, 4, April 1939). The most recent estimate of Gutenberg and Richter shows a radius of the core of 2,920 km., and work on near earthquakes suggests the existence of various crustal layers extending to a depth of the order of 30 km. from the surface of the earth. According to Bullen, if the variation of density between the earth's crustal layers and the central core were continuous, the moment of inertia of the central core wouldhave to be $0 \cdot 57\ Ma^2$, where M is mass of core and a is radius of core. This, being in excess of the value $0 \cdot 40\ Ma^2$ which would hold for a homogeneous sphere, would appear to indicate a virtually impossible distribution of matter inside the central core. Thus some assumption made in obtaining these estimates appeared to need amendment. The amendment suggested by Bullen is that there is a change of material at a depth of the order of several hundred kilometres.

On account of the 20° discontinuity in the travel time graph of P waves from earthquakes which appears to be fairly well established, Jeffreys has suggested either an abrupt change at a depth of 474 km. (uncertainty 20 km.) or an appreciable variation from 300 to 700 km. below the earth's surface. Incidentally, 700 km. gives the depth of focus of the deepest focus earthquake yet recorded. Price and Lahiri have recently suggested a change of material at a depth of approximately 700 km. in the earth on the evidence of variation of electrical conductivity. Following work by Olczak, Jeffreys, Bernal, Benfield and himself, Bullen suggests the following distribution of matter within the earth :

	Depth	Density range
Normal olivine layer	30 474 km.	3·32–3·69 gm. cm.$^{-3}$
Cubic olivine layer	474–2020 km.	4·24–5·57 ,,
Central core	2920–6371 km.	9·77–12·29 ,,

Concerning further density changes within the earth, Gutenberg and Richter have recently directed attention to the possibility of variation within the core itself.

SEVENTY YEARS AGO

NATURE, vol. 1, April 14, 1870

Left-handedness

"J. S." in a letter to the Editor concludes : "Left-handedness is very mysterious ; it seems quite against physiological deductions and the whole tendency of arts and fashion. Prof. Buchanan, of Glasgow, who wrote an able memoir on right-handedness in 1862, thinks that left-handedness may be due to transposition of the viscera, and tells me that his friend Dr. Aitken found such a case. But surely transposition of the viscera must be far rarer than obstinate left-handedness. In cases of left-handed persons which I have examined, the links of the left side were proportionally larger, just as those of the right side are in normal cases. I have also found that left-handedness is hereditary".

Heat Units

THOMAS MUIR, writing from College Hall, St. Andrews, refers, in a letter to the Editor under this title, to the cumbersome terminology used to describe "units of heat", and makes the following comments.

"Define, first, as follows :—A *therm* is the quantity of heat necessary to raise the temperature of 1 gramme of water from 0° C to 1° C. Secondly 1 kilotherm = 10 hectotherms = 1000 therms = . . . , thus having kilotherm, hectotherm, &c., suggestively corresponding to kilogramme, hectogramme, &c., in name as well as in nature.

"Therms and kilotherms, which would probably alone be required in practice, would thus take the place of 'thermal units, centrigrade', 'gramme-water-units', 'kilogramme units of heat', and others more or less lengthy and inexact at present to be found in writing, on Heat and Energy."

Postage on Printed Matter

THE Budget contains an announcement "of the greatest importance to men of science. The postage on printed matter not exceeding 2 oz., and on newspapers not exceeding 6 oz., is to be reduced to one halfpenny. We have waited a long time for this change : not too long, however, to welcome it warmly now it has come, for the tax on all authors of the postage of the scientific papers, copies of which they wish to distribute, has been very great."

AT the anniversary meeting of the Chemical Society held on March 30, the president, Dr. A. W. Williamson, announced in his address that Messrs. Johnstone and Matthey had offered the Society a donation of palladium to be used for the preparation of the first ten Faraday Medals.

THE honour of knighthood has been conferred on Mr. Ronalds for his early researches in telegraphy.

UNIVERSITY EVENTS

ABERDEEN.—On April 4, the honorary degree of LL.D. was conferred on Sir William Jameson, professor of public health, University of London, and Prof. F. A. Lindemann, professor of experimental philosophy, University of Oxford.

FORTHCOMING EVENTS

Monday, April 15

Royal Society of Arts, at 4 p.m.—Dr. L. H. Lampitt: "Science and Food" (Cantor Lectures. Succeeding Lectures on April 22 and April 29).

Tuesday, April 16

Royal Statistical Society (at the Royal Society of Arts), at 5.15 p.m.—Prof. J. H. Jones: "The Report of the Royal Commission on the Distribution of the Industrial Population".

Wednesday, April 17

Royal Society of Arts, at 2.30 p.m.—H. V. Potter: "Plastics as Constructional and Engineering Material".

Royal Microscopical Society, at 3.30 p.m.—Annual Meeting.

Dr. P. N. Bhaduri: "Improved Smear Methods for Rapid Double Staining".

Royal Meteorological Society, at 4.30 p.m.—Prof. P. G. H. Boswell, F.R.S.: "Climates of the Past, a Review of the Geological Evidence" (G. J. Symons Memorial Lecture).

Thursday, April 18

Chemical Society, at 6 p.m.—Prof. R. G. W. Norrish, F.R.S.: "Some Aspects of the Polymerisation of Vinyl Compounds".

Friday, April 19

Eugenics Society (at the Linnean Society), at 5 p.m.—Mrs. Eva Hubback: "Family Allowances".

Saturday, April 20

Association of Scientific Workers (at the Guild of Undergraduates Union, Birmingham), at 3 p.m.—Conference of Industrial Scientists. (Speakers: J. S. Hunter: "Salaries, Cost-of-Living Adjustments, Overtime"; Dr. C. J. Milner: "Holidays and the Five-day Week"; J. Skeel: "The Problems of Assistants, (*a*) General and Economic Problems"; A. G. Ward: "The Problems of Assistants, (*b*) Problems of Technical Education"; Dr. R. E. Priestley: "Science as a Reserved Occupation".

Society of Glass Technology (Meeting at Sheffield), April 16–April 17.

April 17, at 2.30 p.m.—Annual General Meeting.

Prof. L. C. Martin: "The Possibilities of the Electron Microscope".

Dr. M. Benjamin: "An Electron Microscope".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Lecturer in Electrical Engineering at the Croydon Polytechnic—The Education Officer, Education Office, Katharine Street, Croydon (April 16).

Temporary Lecturer in charge of the Department of Physics—The Registrar, University College, Leicester (April 17).

A Graduate Assistant to teach Mathematics and General Science subjects, a Graduate Assistant to teach Mechanical subjects, and a Graduate Assistant to teach Physics, at the West Hartlepool Technical College—The Chief Education Officer, Education Offices, Park Road, West Hartlepool (April 19).

Head of the Department of Electrical Engineering—The Registrar, Portsmouth Municipal College, Portsmouth (April 20).

Engineering Graduate to teach, principally, Mathematics, at the County Technical College, Dartford—F. L. Notley, 11 Essex Road, Dartford (April 20).

Lecturer in Agricultural Chemistry in the School of Agriculture near Khartoum—The Controller, Sudan Government London Office, Wellington House, Buckingham Gate, S.W.1 (quoting Lecturer, A.C.) (April 25).

Head of the Department of Physics and Mathematics—The Principal, Sir John Cass Technical Institute, Jewry Street, E.C.3 (April 27).

Assistant Inspector (man or woman) of Schools in Wales—The Secretary, Welsh Department, Board of Education, Alexandra House, Kingsway, W.C.2 (April 29).

H.M. Inspectors (men) of Technical Schools and Colleges—The Secretary, Board of Education, Alexandra House, Kingsway, W.C.2 (May 4).

Assistant Inspector (woman) in Domestic Science—The Secretary, Board of Education, Alexandra House, Kingsway, W.C.2 (May 4).

H.M. Inspector (woman) of Physical Training—The Secretary, Board of Education, Alexandra House, Kingsway, W.C.2 (May 4).

Imperial Agriculturist at the Imperial Agricultural Research Institute, New Delhi—The High Commissioner for India, General Department, India House, Aldwych, W.C.2 (quoting Appointment 9/1A) (May 4).

Medical Officer (man or woman)—The Secretary, Board of Education, Alexandra House, Kingsway, W.C.2 (May 11).

Head of the Department of Chemistry—The Secretary, School of Metalliferous Mining, Camborne, Cornwall (May 15).

A Senior Lecturer in Civil Engineering, a Lecturer in Civil and Mechanical Engineering, and a Lecturer in Mechanical Engineering, at the Henry Lester Institute of Technical Education, Shanghai—Viney, Price and Goodyear, Empire House, St. Martin's-le-Grand, E.C.1 (May 18).

Engineer with good knowledge of Chemistry and Physics—The Director, British Launderers' Research Association Laboratories, Hill View Gardens, N.W.4.

Draughtsmen (Ship-Constructional, Mechanical and General Engineering) by the Ministry of Supply—The Ministry of Supply (S.E.3b), Adelphi, W.C.2 (quoting Appts. 026/S.E.3b).

Vol. 145 SATURDAY, APRIL 20, 1940 No. 3677

LOCATION OF INDUSTRY IN GREAT BRITAIN

THE Royal Commission on the Distribution of the Industrial Population, under the chairmanship of Sir Montague Barlow, was appointed in July 1937, mainly in consequence of the concern at the slow recovery of the Depressed Areas and the steady drift of population to London and the Home Counties. The views so strongly expressed by successive Commissioners for the Special Areas, without apparent effect, had by then been powerfully reinforced by defence considerations. The strategical dangers to which the whole country was exposed by over-development in its most vulnerable part could no longer be ignored, and the possibility of experimenting in national planning had at last to be considered seriously by the Government.

When the Royal Commission was appointed, an inquiry into the location of industry undertaken by a group of Political and Economic Planning had already reached an advanced stage. The latter inquiry, in view of its relation to the work of other P E P groups, was nevertheless carried to a conclusion and its report was published in March of last year. It is not surprising, therefore, that the recently published report of the Royal Commission, a summary of which appears elsewhere in this issue, provides little additional information, but nevertheless it gives us an able and well-balanced survey of the situation.

Both in the basic facts which are set forth and in the conclusions and recommendations deduced from them, the two reports have much in common. Where the Planning Group of P E P recommends the creation of a permanent Industrial Development Commission for the specific purpose of guiding the location of industry and advising the Government on the subject, the majority report of the Royal Commission recommends the appointment of a National Industrial Board, with mainly advisory powers except in regard to regulation of industrial location in London and the Home Counties. There is, however, a wide divergence of opinion among the members of the Royal Commission in regard to the functions to be exercised by the central authority. Three of the ten members who sign the majority report do so with reservations which would bring the functions of the proposed Board closely into line with those of the Development Commission recommended in the P E P report. The remaining three members of the Commission go even beyond the P E P report, which suggested that a senior Cabinet Minister without departmental duties should be responsible to Parliament for the activities of the Commission, and recommend the establishment of a new ministry, taking over not only the functions of the Commissioners for the Special Areas, but also some of the functions of the Ministry of Health and Ministry of Transport.

This sense of urgency and note of conviction, which characterize both the reservations and the minority report, give a value and reality to the outcome of the Commission's labours which would otherwise be sadly lacking. Without them it could scarcely be said that the report does more than give us a fresh and convenient presentation of facts already widely known, leading to conclusions previously reached by many thoughtful observers and students of problems of industrial location or planning. The bare majority of the Commission appears to falter just where decision and action are most needed, and the ably argued reservations of Prof. J. H. Jones, Mr. G. W. Thomson and Sir William Whyte in the minority report are likely to carry much more conviction with scientific workers.

The signatories of the minority report regard the excessive concentration of population in London and other large conurbations as more a symptom of the main disease than as an evil in itself, although socially and strategically they agree with the other commissioners that it is an evil which requires remedying at the earliest possible moment. They urge, therefore, that positive action by way of regulating new industrial development throughout Great Britain is a more essential and effective way of treating the problem than simple restriction of the industrial growth of a particular area. A beginning must be made in treating the country as a social and economic unit as well as a political unit.

The logic of such a policy can scarcely be denied if there be agreement on the basic facts from which it is derived. Moreover, only continuous study by the new Board of the problem of achieving a well-balanced industrial society can obviate the creation or perpetuation of areas of great distress in the near future. The facts assembled in the report should finally dispose of any lingering contention that we can rely on unguided or uncontrolled private industry in such matters without detriment to the social, economic, and strategic interests or amenities of the nation. The unassailable fact demonstrated by this report, like that of the PEP report, is that apart altogether from the difficulties and complications of co-ordination and clashing of interests, neither the industrialist nor the individual Government department has usually anything like the amount of information required for a sound decision as to location. Decisions based on a partial knowledge of the facts have been invalidated by unforeseen developments elsewhere with consequences no less disastrous to the enterprise itself than to the district and community in which it was mistakenly placed.

For such reasons as these there is general agreement that a beginning should be made with London ; but the experience gained with restrictive powers in that region should be used from the start as a guide in preparing a scheme to be applied to the whole of Great Britain. No district should be considered or dealt with other than as one part of a national problem, and the whole experience of the past few months of war endorses the urgency of the minority argument or reservation on this point in the report. Accordingly, once the necessity of conferring immediate executive powers on the proposed Board in respect of London and the Home Counties is admitted, it appears to be illogical to withhold the general executive powers which are advocated by six out of the thirteen members of the Royal Commission.

The difference between the bare majority and the remaining members of the Royal Commission appears to be much more profound than is indicated by mere reservations. Having regard to the urgency of the problem, accentuated by all the disturbance of civil life which the War has since occasioned, the choice between advisory powers and executive powers may make all the difference between success or failure in the formulation and execution of an adequate plan.

This point of view is endorsed by the experience of the Commissioners for the Special Areas. Evidence submitted to the Royal Commission showed not only that the Commissioners had made the fullest use of their powers and opportunities, but also that their powers had been too rigidly defined and were too restricted in scope. The solution to the problem of the Special Areas does not necessarily lie within the defined geographical limits of such areas, any more than the problem of location of industry can be separated from the national problem of persistent unemployment. Moreover, the Commissioners for the Special Areas are not empowered to do more than endeavour to remedy—or mitigate—a serious evil that has already appeared. Anticipation and prevention lie outside their province.

These considerations led the minority of the Commissioners to recommend that the essential powers and responsibilities of the Commissioners for the Special Areas should be transferred either to the new Board recommended in the majority report, or to the new Ministry recommended in the minority report, and that they should be extended to cover the whole of Great Britain. The basic purpose of such extension is to provide preventive rather than curative action, so far as possible, and the intensity of armament production at the present time emphasizes the warning that, in the absence of such preparation for the future, the problems of the past will reappear, and become even more serious in extent and more difficult to solve.

This is indeed one of the dominant notes throughout the reservations and the minority report, and a basic consideration in putting forward recommendations for wider executive powers and immediate action. A policy of drift is likely now, even more than when the report was written, to lead to the perpetuation and exaggeration of existing evils. The continuance of ineffective control may also result in irremediable damage to the countryside and amenities through unrestricted despoliation and haphazard development arising out of evacuation, decentralization and the building of camps, whether civil or military.

The salient feature in the existing situation is that little, or in any event insufficient, attention has been given to the problem of the best distribution of industry in Great Britain as a whole. Not only are the town planning schemes local by definition, but also much of the basic knowledge required to guide industry in the choice of sites is lacking. The necessity for unified research into the problem of distribution on a national scale is widely recognized. On this, and on the necessity for a unified plan of distribution based on the results of such research, and for effective control meanwhile of such changes in distribution as must continue to take place in the interests of trade, the Royal Commission is virtually unanimous. The minority only differs from the majority in considering that this task, which is both national and local, is of sufficient importance to call for the creation of a new separate Ministry, on the same principle as that on which separate Ministries have been created in the past for the partly national and partly local services of education and transport.

The divergence of views on the Commission in regard to the urgency and machinery of Government action should not be allowed to overshadow the basic fact that the Commission is unanimous in its nine main conclusions as to the objectives of that action. Moreover, the evidence demonstrated the existence of a large body of opinion in favour of some regulating action along national lines and in the national interest. It is indeed possible to regard the essential difference between the majority and minority recommendations as consisting in the greater regard had by the former to action which is immediately practicable, rather than to that which is theoretically desirable but would demand further educational effort to secure adequate support.

If, therefore, the wider vision and longer range objectives which characterize the minority recommendations are kept in mind, adoption of the majority report and action along the lines advocated by it is more likely than not to prove a stepping stone to the wider and more extensive powers contemplated by the remaining Commissioners. The task of education can proceed *pari passu* with such action, and the impetus to regionalism which the report can scarcely fail to give—which has indeed already been given by civil defence and other emergency measures in war-time—should further assist in that process.

What has to be kept in mind is the importance of immediate action. The report must not be merely shelved until after the War. The nation cannot afford to leave great industrial areas of the country derelict and allow development to repeat the process elsewhere. There is no guarantee that the new and expanding industries of to-day will not be the depressed industries of to-morrow if allowed to develop without control. Moreover, developments proceeding in war-time require co-ordination and control if the problem is not to become even more intractable, with further waste of national assets, spoliation of amenities, injury to national health and destruction of the countryside.

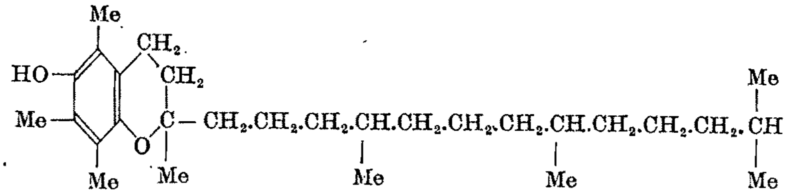
The report has therefore the strongest claims on the attention of all who are concerned with the scientific utilization and conservation of national resources in the widest sense. The co-operation of scientific men is essential in much of the basic research work required and in the elaboration of the necessary plans for development. On a score of technical questions it will fall within their competence to give the appropriate data. Above all, the problem must be considered in relation to that task of reconstruction which will confront us urgently at the end of the War, and possibly the more imperatively the longer the War lasts. We cannot afford to wait until irreparable damage is done, and solutions have to be found urgently and decisions made under duress and with no sound basis. The extensive and realistic research and planning upon which peaceful change depends, whether in national or international affairs, cannot be improvized in a moment. The location of industry is typical of those problems which must be visualized and handled before they become chronic or acute, and before their reactions on other problems multiply. Already, as the report shows plainly, the maldistribution of the industrial population of Great Britain has reached a point when it may easily become intractable.

The problem is a vital part of our war effort, and if that is to attain its maximum efficiency and the subsequent task of reconstruction is not to be hindered, it must be faced at once. The report of the Barlow Commission points out certain possible lines of immediate advance, and provides fresh material with which to win the support of the community for progressive measures in dealing with the distribution of the industrial population of Great Britain.

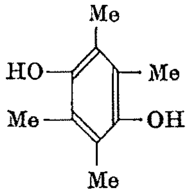
VITAMIN E

Vitamin E
A Symposium held under the auspices of the Food Group (Nutrition Panel) of the Society of Chemical Industry on Saturday, 22nd April, 1939. Pp. viii + 88. (London: Society of Chemical Industry, 1939.) 5*s*.

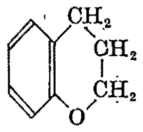
VITAMIN E was discovered in 1922. Experiments which had been conducted in three different laboratories in the United States revealed that female rats failed to reproduce when kept on certain artificial diets, although these contained the four vitamins then recognized, A, B, C and D. Evans and Bishop of the University of California pointed out that another vitamin was involved. It was named first vitamin X and later vitamin E.



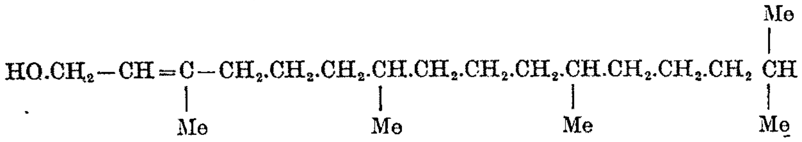
Vitamin E (α-tocopherol)



Duroquinol

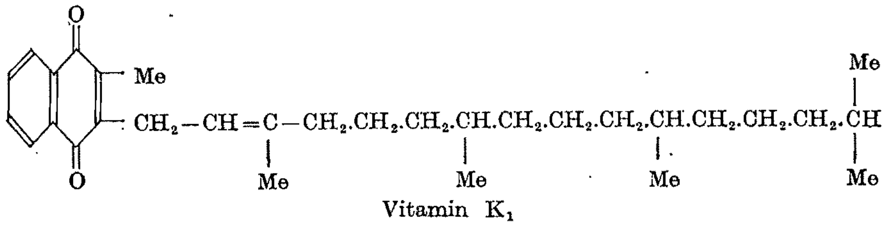


Chroman



$$HO.CH_2-CH=\underset{Me}{C}-CH_2.CH_2.CH_2.\underset{Me}{CH}.CH_2.CH_2.CH_2.\underset{Me}{CH}.CH_2.CH_2.CH_2\ \overset{Me}{\underset{Me}{CH}}$$

Phytol



Vitamin K₁

STRUCTURAL FORMULÆ, SHOWING RELATIONSHIPS BETWEEN VITAMIN E (α-TOCOPHEROL), DUROQUINOL, CHROMAN, PHYTOL AND VITAMIN K₁

The first detailed study of the vitamin was made by Evans and Burr. They showed that in the absence of the 'anti-sterility vitamin', as it was commonly called, gestation was terminated after about two weeks by the resorption of the fœtus. This sterility of the female could be cured if vitamin E was restored to the diet. In the male rat a degeneration of the germ cells occurred, which was less readily curable, or even incurable. Evans and Burr found that the vitamin was present in a number of natural vegetable oils such as those of wheat germ, rice germ, cotton seed and in lettuce leaf. It occurred in the unsaponifiable fraction of the oils. Animal products contained only traces.

For about a decade after the publication of Evans and Burr's monograph in 1927, there was little further advance to record. Then in 1936 Evans and his colleagues announced that they had at length succeeded in isolating from wheat-germ oil two substances which possessed the biological properties of the vitamin. These they named α-tocopherol and β-tocopherol, signifying 'alcohol promoting child-birth'.

In the past couple of years progress has been striking. Not only has the structure of α-tocopherol (and of related substances) been established, but also it has been synthesized and the synthetic product has been proved to be as active as the natural one. α-Tocopherol is related structurally to duroquinol, and has a fused ring system of the chroman type, an interesting feature being the presence of the phytol residue which is found also in chlorophyll and in vitamin K_1, the so-called coagulation factor. In other directions, too, there have been important developments. For example, we now know that a continued lack of vitamin E leads to a variety of ill-effects in addition to sterility. Then again, methods have lately been introduced for the chemical assay of the vitamin which in time may be able to replace the laborious biological test. Or, to take a third example, much interesting work has been done on the relation between chemical structure and biological specificity.

There was an obvious need to bring together and collate all these recent achievements, and the indefatigable officers of the Nutrition Panel of the Society of Chemical Industry put all biologists and chemists in their debt when they organized last spring a symposium on vitamin E, which many of the leading workers of the world attended and to which they contributed authoritative accounts of their investigations. The Society has done well to publish *in extenso* the proceedings of this symposium, and the booklet recently issued is virtually a monograph dealing with vitamin E from almost every angle. The editors, Mr. A. L. Bacharach and Prof. J. C. Drummond, have carried out their task conscientiously and effectively, and the value of the work is increased as a result of their efforts of co-ordination and particularly by the provision of the complete alphabetical bibliography.

The text is divided into three parts dealing with the chemical, physiological and clinical aspects respectively.

In the opening paper, Prof. A. R. Todd gives a valuable review of the organic chemistry of vitamin E and related substances. The question of biological specificity is next discussed, by Prof. P. Karrer of Zurich and Dr. F. Bergel. Their main conclusion is that for maximum biological activity the presence of the long aliphatic side chain is essential. In the aromatic nucleus the presence of all three methyl groups is most favourable, for with but one methyl group there is only a low degree of activity. Ethyl has an unfavourable influence. Drs. Emmerie and Engel, of the University of Utrecht, give an account of the promising chemical test which they have introduced, depending on the reduction of ferric chloride by the vitamin and the estimation of the resultant ferrous ion by means of 2 : 2′-dipyridyl. This reaction can apparently be made relatively specific, and will estimate as little as 5 μgm. of tocopherol; it can probably be applied to blood. A critical comparison of this and other chemical and biological methods is given by Dr. E. Lester Smith and Mr. R. Bailey. They found that the chemical methods are prone to overestimate the activity of concentrates but to underestimate that of oils.

On the physiological side, one of the most interesting suggestions is that vitamin E is needed for the normal functioning of the anterior lobe of the pituitary gland. Evidence in favour of this theory is well set out by Dr. S. W. F. Underhill, but the connexion is by no means universally accepted. For example, Prof. J. C. Drummond in his lucid review prefers to take a more cautious line, and as he says: "We are still fumbling in the dark trying to find some clue to the hormonal disturbance responsible for the characteristic failures of the reproductive system in vitamin-E deficient rats." In this connexion Drummond alludes to the work of Karl Mason, another contributor to the symposium, who has cogently pointed out that the type of testicular degeneration seen in vitamin-E deficiency is unique and does not at all completely resemble that which can be produced by hypophysectomy or that following prolonged administration of œstrogenic substances.

A few years ago, vitamin E was known only by the effect of its deficiency on reproductive function. Now at least half a dozen further symptoms are recognized, of a rather ill-assorted character. These include muscular dystrophy, degeneration of muscle fibres leading to discoloration of uterus and seminal vesicles, a characteristic degeneration of the convoluted tubules of the kidney, a so-called 'alimentary exudative diathesis', subnormal growth, and failure to store vitamin A normally in the liver. Dr. Thomas Moore and his colleagues deal succinctly with some of these aspects of vitamin-E deficiency. It must be admitted that we are still without any explanation of the cause of these surprisingly varied manifestations. The physiological section of the symposium closes with an able contribution by Mr. A. L. Bacharach discussing the whole philosophy and application of biological standardization. He rightly condemns 'biological units', such as 'rat units', 'mouse units', etc., and remarks: "In the modern sense of the word this is not a unit at all; it is simply the reciprocal of a dose that had a certain effect on a certain animal at a certain time". The objection to 'biological units', of course, is that animals vary. "Animal variation is merely a polite term for the integrated incompetence of the investigator, its effect is to deprive the so-called 'biological unit' of even roughly quantitative significance." The moral, needless to say, is to use specified amounts of fixed standard preparations as units.

On the clinical side, it must be confessed that most will feel themselves forced, however unreadily, to agree with Prof. F. J. Browne that the claims which have been made remain unproved for the greater part. True, it has been contended that therapy with vitamin E has given 75 per cent of successes in habitual abortion, or 68 per cent in threatened abortion, or 41 per cent in defective lactation. There is, perhaps, nothing inherently unlikely or even improbable in these claims. The only 'snag' is the absence of untreated negative controls. Browne points out, on the authority of Malpas, that after one, two or three spontaneous abortions, the chances of the next pregnancy being carried to term are 78, 62 and 27 per cent, *even in the absence of any specific treatment.* This has scarcely been taken into account in assessing the value of vitamin-E therapy. Browne, indeed, refers to a controlled test by Boycott in which the seven negative controls all 'responded' although receiving no treatment at all! Still more recently, vitamin E has been recommended for the treatment of muscular dystrophies and even of tabes. The last-mentioned disease seems to be included more as a matter of faith than as a result of successful accomplishment. In the opinion of the present reviewer it would be a help for the future if the conjecture of a deficiency of vitamin E in a given disease, and the accompanying suggestion for therapy, could be backed up by chemical tests on the patient's blood to establish the actual occurrence of a low level of nutrition.

It has not been possible in this review to touch on all the varied ground covered in the symposium, but it must be evident that no worker on vitamins and nutrition can afford to be without it.

LESLIE J. HARRIS.

THE DOMAIN THEORY OF MAGNETIZATION

Ferromagnetismus
Von Prof. Dr. R. Becker und Dr. W. Döring. Pp. vii + 440. (Berlin: Julius Springer, 1939.) 42.60 gold marks.

IT is very unfortunate that this important work should have appeared at such an inopportune moment in the world's history, when it will be difficult for most of the English-speaking peoples to obtain copies of it. Those of us who had the pleasure of meeting Prof. R. Becker at the 1939 Conferences on Magnetism in Bristol and in Strasbourg must sympathize with him in no small measure. In this work Dr. Döring and he have put forward in a very complete manner the whole series of interesting ideas on the processes of magnetization which have emanated from Göttingen during the present decade.

Prof. Becker gave a series of lectures in the winter of 1934–35 under the auspices of the Technische Hochschule at Berlin to an audience consisting in the main of technicians, who, no doubt, keenly appreciated accounts of the work of Becker and his collaborators on the relation between stress, magnetostriction and direction of magnetization as exemplified by experiments on nickel under tension.

The present book owes its origin to the success of those lectures. Its scope may be summarized as follows. It seeks to give a brief survey of the Weiss conception of domains in a ferromagnetic which are spontaneously magnetized more or less to saturation, and of those problems of academic interest, such as the variation of spontaneous magnetization with temperature, upon which the conception bears. It seeks mainly, however, taking the Weiss conception for granted, to explain those magnetic properties of ferromagnetics which are of great technical importance, such as the shape of the hysteresis curve, in terms of the alignment or growth of Weiss domains in favoured directions. In fact, the book might almost be described as a treatise on the technical aspects of the domain theory of magnetism. The reviewer was therefore a little surprised to find no mention in the book of Stoner's stimulating discussion of the effects of domain size, although it is only fair to add that the effects of domain size are at present of less interest in technical than in academic work on magnetic saturation, and the reviewer has noticed no other omission of any import.

The book does not avoid mathematical arguments whenever necessary, and although these are profusely supported with experimental results, the book requires some power of concentration of the reader if it is to be read with profit. However, a fundamental discussion of the different processes which play a part in technical magnetization, in magnetostriction, in the determination of high initial permeability, in Barkhausen discontinuities, in permeability at high frequencies and so on, cannot be treated with ease. The authors have indeed performed a most useful service in placing the present theory before us in such a complete manner and in correlating so many experimental facts with the theory. Some of the theory clearly needs amplification; for example, what may be termed the Döring theory of large Barkhausen discontinuities is really a theory for a metal in two dimensions only, and, as Stoner pointed out at the Bristol Conference, it is difficult to picture what happens when we think of the domains in the three dimensions of the solid material. Again, in spite of all that has been written in the publications of learned societies about the heat liberated in hysteresis processes being equal to $\int H.dI$, we still cannot calculate the quantity of heat which is dissipated in a piece of iron when it is subjected to a partial change in magnetization, as distinct from a complete cycle, under normal experimental conditions.

A valuable section of some fifty pages is devoted to commercial ferromagnetic materials and their applications, wherein the problems of precipitation hardening and the effects of tempering in the presence of a magnetic field are discussed. The book is of definite interest to all concerned with technical applications or the production of ferromagnetics. It deserves every success, and one cannot but deplore that the increase of our knowledge which the authors have tried to bring about should be so unfortunately held up by others of their tongue but not of their spirit. L. F. Bates.

A THEORY OF PROBABILITY

Theory of Probability
By Dr. Harold Jeffreys (International Series of Monographs on Physics.) Pp. vii + 380. (Oxford: Clarendon Press; London: Oxford University Press, 1939.) 21*s.* net.

In his "Scientific Inference", Dr. Jeffreys has already adumbrated his approach to the theory of probability. The present book is a more systematic presentation of his views, beginning with the formulation of axioms, developing a theory of probability, describing and illustrating its use in testing significance and in estimation, and concluding with two chapters on the weaknesses of other theories and on some general scientific questions.

Probability to Dr. Jeffreys means something more than the proportion of events of a certain type in a series or an aggregate; he takes it in the wider sense of a measure of degrees of reasonable confidence in the truth of a proposition. His principal problem in his treatment of the foundations is accordingly to establish the validity of representing degrees of reasonable confidence by numbers. He overcomes it by an axiom to the effect that for any three propositions, p, q, r, the statement "on data p, q is more probable than r" has a meaning—in other words that probabilities are orderable. Now, most statisticians would accept this axiom without question, because their probabilities are *defined* as numbers; but one may fairly hesitate over the claim that Dr. Jeffreys' probabilities, which relate to attitudes of uncertainty of mind, can be ordered. There does not seem to be much in our present knowledge of mental states to support an assumption that judgments in probability are linear.

If Dr. Jeffreys' first axiom is accepted, the rest of his foundational material follows naturally enough. Having got his probabilities ordered in a straight line, he succeeds in imposing a metric on them, and in deriving the ordinary rules for addition and multiplication. He also obtains as a theorem the result which has caused so much trouble since Bayes gave it in 1763,

$$P(q_r \mid pH) \propto P(q_r \mid H) \quad P(p \mid q_rH),$$

that is, the probability of q^r given p and H is proportional to the probability of q_r given H multiplied by the probability of p given q_r and H. Dr. Jeffreys calls the factor on the left in this expression the *posterior probability*, the first factor on the right the *prior probability* and the remaining factor the *likelihood*. This result is the foundation stone of his theory. It is, he says, the chief rule involved in learning from experience.

In order to make any practical use of Bayes' theorem it is essential to decide on the values to be assigned to the prior probabilities. Bayes and Laplace postulated that in the absence of definite knowledge they were to be assumed equal. This "equidistribution of ignorance" has been relentlessly attacked in recent years, chiefly by statisticians; but Dr. Jeffreys defends it in a novel and interesting approach. The statistician's criticism is misconceived because he insists on thinking in terms of frequencies. But when Dr. Jeffreys, considering a parameter θ which may vary from $-\infty$ to $+\infty$, writes for the prior probability $P(d\theta \mid H) \propto d\theta$, he does not mean that an assumption is being made about the equidistribution of θ in the universe. He merely means "I know nothing about θ". It is his way of giving to airy nothing a local habitation and a name. This avoids most of the statistician's criticisms; but it gets Dr. Jeffreys into some new difficulties. For example, when θ is known to lie between zero and infinity, the corresponding way of saying nothing about its prior probability is $P(d\theta \mid H) \propto d\theta/\theta$. Why it should be necessary to use the notion of a reciprocal in order to express ignorance about a parameter is far from clear to me, although Dr. Jeffreys puts up a long case for the formula.

In his treatment of estimation and significance tests Dr. Jeffreys is concerned with laws containing a certain number of unknown parameters. A significance test is a method of deciding whether any given law is adequate to express observational data, or whether further parameters are required. Estimation is the determination of the most probable values of such parameters as are shown by significance tests to be necessary. Dr. Jeffreys' discussion of the many problems involved is difficult to describe succinctly; but his methods all involve a comparison of the probability of a hypothesis q with that of not-q. The ratio of these two probabilities is denoted by K. It corresponds to what the orthodox would describe as the odds in favour of q.

For the expression of K in numerical terms it is necessary to determine the prior probabilities of hypotheses. Suppose, for example, a test is being made whether a given law fits given data. It is assumed that any new parameter α which might be required is so chosen that the given law is reproduced if $\alpha = 0$. In such a case Dr. Jeffreys would assign half the prior probability to the hypothesis $\alpha = 0$, and distribute the remainder equally over the range of α. Thus $K = P(\alpha \mid pH)/P$ (not-α $\mid pH$) where p is the observational data. By Bayes' theorem the probabilities of α and not-α are expressible in terms of the assumed prior probabilities and the calculable likelihoods; and hence K results.

Anyone who rejects this approach can console himself with some comparisons made by Dr. Jeffreys with alternative procedures in use by statisticians, particularly the method of maximum likelihood. It is shown that for large samples the latter method gives much the same results as Dr. Jeffreys'. The hypothesis which maximizes the likelihood will, within permissible limits, be the one with the greatest posterior probability. And so the bridge between Dr. Jeffreys and Prof. R. A. Fisher is built—for large samples.

Dr. Jeffreys' criticisms of the frequency theories of probability centre around the necessity of justifying the application of the frequency definition to practical series by an appeal to probability itself. Dr. Jeffreys rejects such theories; and indeed it is hard to see how any writer on fundamentals can tolerate the intellectual discomfort which some of them arouse. But there is a Scylla to this Charybdis. Dr. Jeffreys' probabilities are measures of belief, not frequencies. Why, then, should he accept them as the basis of rational action? By assuming that, on the whole, what we believe is right, or as the author has put it elsewhere, "It is possible to learn from experience". It is essential for his theory that, proverbs notwithstanding, the expected usually happens. What is the basis for our ready acceptance of this postulate? The adherent to frequency theories will claim that it is an extrapolation of experience of the frequencies of events.

The reactions of one writer on probability to another being naturally exothermic, it is to be expected that Dr. Jeffreys' strictures on the naiver theories of probability will not pass unchallenged. It would be a great pity if the importance of the issues at stake were to be fogged by ill-considered criticism. Dr. Jeffreys' views deserve the most serious study. They may not be right; but they are more tenable than many statisticians have been willing to concede in the past, and it is hoped that this book will be widely read.

M. G. Kendall.

PLANT PERSONALITIES

Plants with Personality
By Patrick M. Synge. Illustrated with Plates from Dr. Thornton's Temple of Flora and with Drawings by John Nash. Pp. 244 + 20 plates. (London: Lindsay Drummond, Ltd., 1939.) 12*s*. 6*d*. net.

THIS is not everyone's book. Mr. Synge is a mystic and looks at the world of plants through metaphysical spectacles. His introduction would do credit to a treatise on Hegelian idealism. Plants, for him, "live, they grow; they are real, yet they are something more than real and we can all see it". The reader who accepts this approach, and the rather highly coloured writing to which it leads, will find much in the volume to entertain him.

Mr. Synge has selected a series of plants which appeal to him as possessing "definite personalities", and has described his reaction to them under such chapter headings as "Sun Lovers of South Africa", "Fierce Wonders from Chile", "Children of the Mexican Sun", etc.

Mixed with the purple patches, the author contrives to convey a considerable amount of valuable information on the history, distribution and horticultural treatment of his subjects. Mr. Synge's facts are usually accurate. In his section on the *Victoria regia*, however, he does not describe the remarkable change of colour from pure white to deep rose as the flower fades, and there are a number of misprints, including *Œnothera teraxicifolia* for *taraxicifolia,* despite a note on the derivation of the word.

The author has seen many of the plants mentioned himself in their native countries, and the best chapter in the book is, perhaps, that on the giant plants of the East African mountains which he visited recently with the Natural History Museum expedition.

One of the most striking features of the book are the illustrations. These are taken partly from Thornton's "Temple of Flora", partly from other botanical works, partly from original drawings by John Nash and partly from photographs. It is a pity that the source of each illustration is not more clearly indicated. John Nash's drawings are delightful, that of *Puya alpestris* being a masterpiece of its kind. Mention might have been made of Miss North's painting of Puya in her gallery at Kew.

As a bedside book for gardeners and botanists, Mr. Synge's volume will no doubt appeal to a wide circle of readers. J. S. L. Gilmour.

PHOTOCHEMISTRY

Photochemistry and the Mechanism of Chemical Reactions

By Prof. Gerhard K. Rollefson and Dr. Milton Burton. (Prentice-Hall Chemistry Series.) Pp. xiv + 445. (New York: Prentice-Hall, Inc., 1939.) 5.75 dollars.

The task of writing a modern text-book of photochemistry is no easy one. To keep the volume within reasonable confines is almost as difficult a problem, since the limits to which the author must work are not readily defined. If the author does not presuppose it, a considerable discussion must be devoted to physical principles, especially on the spectroscopic side. Again, photochemistry now reaches far into biology, and the question arises as to whether such a topic should be included in a book mainly compiled for use by physical chemists. Another subject with which it is indissolubly linked is reaction kinetics, for it is difficult to dissociate photochemistry from kinetics, having regard to the fact that there are scarcely any simple photo reactions in the sense that the primary process represents the chemistry of the whole reaction. It is not going too far to say that a large part of photochemistry is now a branch of general reaction kinetics.

In this volume Prof. Rollefson and Dr. Burton have steered a careful middle course. They open with three chapters giving a sufficient account of spectroscopy, yet not enough to frighten off the reader who is concerned only with the more purely chemical aspects of photo-reactions. Similarly, the chapter on reaction kinetics leads the reader without difficulty into the more detailed discussions in the later parts of the book. Then follow the chapters forming the substantial fraction of the book. Nowadays the arrangement is largely a matter of personal choice, for there is no sufficiently rigid framework within which can be fitted the descriptions of the individual types of reaction. The simplest photo-reaction is probably that occurring in alkali halide crystals. Here recent work has added a new and important chapter to photochemistry. Then follow chapters on the photolysis of inorganic compounds, organic molecules, molecular rearrangements, photosensitization and typical chain reactions—all in the gas phase. In these chapters much of the older material is eliminated and only the more recent papers discussed. This is region of great difficulty since there are many reactions to be discussed, but each gets its due quota of space. Even in 200 pages only superficial discussion of any one may be given. It would have been a better plan to have discussed thoroughly and completely a few well-known examples at the expense of the omission of less well-investigated systems. The adoption of a more critical attitude would have done photochemistry no disservice. The specialist would welcome such discussion even though he might not agree with the conclusions. The beginner would be made to realize that the subject is more difficult than he is led to suppose.

The last four chapters of the book deal with topics which are only now in an early stage of development. Addition reactions, the oxidation of aldehydes, polymerization reactions in liquids and heterogeneous photo-reactions are all fairly extensive fields of research in which there is much to be done before a really coherent account may be put in a text-book. A very useful practical appendix completes the volume.

Here then is a book which allows anyone with no specialist knowledge easy access to photochemistry. Those who wish to find what is known about an individual reaction will discover the required information. Those who are already familiar with the subject will find much food for further thought and experiment. H. W. Melville.

PEACE-MAKING AFTER WAR[*]

By The Right Hon. Lord Eustace Percy, P.C.

I AM to discourse on peace-making, but this does not mean that I am going to formulate what are generally called 'peace terms'. On the contrary, I must begin by a warning against programmes of that kind. Peace-making is a process, not an act. It is a process which has been interrupted by war and must be resumed after the so-called 'treaty of peace' is concluded. For such a treaty can do little more than record the desire of the parties to adjust their interests and their ideals in future by peaceful, rather than by warlike, means. The adjustment itself must occupy years. The peace terms may hinder it, if they inflict serious injury, moral or material, on one party; but they cannot do much to further it. The attempt to take advantage of war-weariness, or of a peace congress representing a number of nations, in order to formulate far-reaching safeguards for future peace, has seldom, if ever, been successful.

It follows that the first condition of successful peace-making is that the statesman who attempts it should be left doubly free. He should be left free by his own people from precise pledges as to the contents of the peace treaty; he should be left free by the peace treaty from hampering commitments as to his future policy. He must have behind him the public opinion of his people; but it must be an opinion about the contribution which his people should make to peace, rather than about the kind of peace they would like to have. In peace, as in war, the 'wishing-well' temper of mind is useless. In war, a will to victory is a determination to keep armies in the field, not the dream of seeing them march into the enemy's capital. Peace-making requires a no less continuous effort, no less readiness both to sacrifice immediate advantages and to forgo ultimate dreams. The only sound purpose of discussions about peace-making in time of war is to form a public opinion of this kind, by indicating what are the real causes of the particular war and what, consequently, are the sacrifices which peace-making may demand.

The historian's first, and most obvious, contribution to such a discussion is to remind men of the facts of yesterday, which are in large measure the facts of to-day and to-morrow. From the historian's point of view, the chief evil of war or revolution is not so much its crude immediate effect in human misery as its tendency to produce in the human mind an illusion of emancipation from the quite recent past. Of course, war does change facts; it may kill an old institution, for example, and stimulate a new movement. But, broadly speaking, it kills only what is already decayed, and stimulates only what is already alive. There is no release from the past; the facts of 1942 will not be materially different from the facts of 1938.

What may, we hope, be different in 1942 is our power of understanding what the facts really are; and for this we need to be reminded of a remoter past. In this lies the historian's second, and most important, contribution to the discussions of the hour. The point I chiefly want to make, and to illustrate, is the importance of reckoning our present position in the world's history by reference to a past remote enough to dwarf our contemporary assumptions into their true proportions, and to prepare us for the unexpected forms in which history repeats itself over long periods. If there is anything more dangerous than the illusion of emancipation from the *facts* of the immediate past, it is the tendency to attribute eternal validity to the *ideas* of the last century or two—to measure the whole 'march of mankind' by the eighteenth-century standard of 'enlightenment' and the nineteenth-century standard of 'utility'. It is, no doubt, comforting to compare modern knowledge with that of Aristotle or Seneca or Aquinas; it is not so comforting to reflect that an increase in knowledge may mean only an increase in crude power, that it may fit us only to tutor more ambitious conquerors than Alexander, to advise worse tyrants than Nero, and to herald a more complete collapse of civilization than that which overtook Papacy and Empire in the fourteenth century.

Let me then try to suggest another possible view of European history in relation to present problems.

A dweller on the Roman Wall may, perhaps, be forgiven if he takes as his starting-point the death of the Emperor Hadrian in the year 138. The Rhine-Danube frontier of the Roman Empire, as he left it, has become to-day almost the frontier of Christian civilization—pushed back in the west on the middle Rhine and between the Rhine and the Upper Danube, pushed forward a little in the east between the Danube and the Theiss, but only seriously breached at its centre in Austria. It was there that, twenty-three years after Hadrian's death, the Marcomanni first broke through to the Adriatic; it was there that, exactly eighteen hundred years after his death, another Germanic invasion carried paganism south from the Danube to the Drave. This threatened frontier is to-day the frontier of the British, as it was of the Roman Empire, as the gathering on it of distant armies has reminded us. It would be fanciful to press the analogy, and tedious to qualify it; but it may serve as a point of departure.

---

[*] From the Friday evening discourse delivered at the Royal Institution on March 1.

During all these eighteen hundred years, the history of Western civilization has been the history of folk wanderings. For the first nine hundred, down to the establishment, in the second half of the eleventh century, of Norman rule in England and Sicily, of Seljuk rule in Asia Minor, and of Teutonic colonization among the Slavs on the eastern marches of Germany, the sequence of migratory conquest and settlement was almost unbroken. There was an interval of some two hundred and fifty years between the last Teutonic and the first Scandinavian waves of conquest, between the end of the sixth century, when the Lombard Kingdom had been established in Italy, and the middle of the ninth, when the Danes invaded England and the Varangars threatened Constantinople. But midway in that interval the high tide of Arab conquest almost reached the Bosphorus and the Loire, and the age of Charlemagne was but a 'gap between two lightnings'.

The first real interval of consolidation came at the end of the eleventh century. It, too, lasted for about two hundred and fifty years, from the First Crusade to the first Ottoman landing on Gallipoli in 1356. Again, it was broken midway by the Tartar raids; the frontiers of Christian civilization were still hotly contested in Spain, North Africa and Palestine; internally the old Teutonic and Scandinavian tradition of the 'southward thrust' took a new political form in the two great struggles for ascendancy, between Empire and Papacy in Italy and between Plantagenet and Capetian in France. But this troubled interval, especially the thirteenth century, did mark the consolidation of the new peoples of Europe into one society with its own distinctive culture, a single *Kulturgebiet*; it did give freedom of movement, within that society, to the cleric, the merchant, the craftsman and the scholar; it did give opportunity to the rising cities of Italy and Germany to translate old migratory instincts into terms of international commerce. By the end of the period, Genoese ships had attempted the circumnavigation of Africa and a Genoese trading station had been established in South China; population had begun once more to outgrow the resources of medieval agriculture; and, now that the safety valve of the Crusades and the Moorish wars was closed, and Papacy and Empire had fought each other to a standstill, the fighting class was looking for new opportunities of adventure.

The next one hundred and seventy-three years were perhaps the darkest of European history. The resumption of migration was postponed by the Black Death, which nearly halved the population of the Continent. Simultaneously, Europe became the victim, instead of the agent, of a new migratory conquest. Between 1356 and 1529 the Ottoman invasion crept, in successive waves, to its high-water mark beneath the walls of Vienna. The last, and most destructive, decade of its advance was the decade which saw also the first circumnavigation of the globe, the Spanish conquest of Mexico, and the discovery of Peru.

From that moment, for four hundred years, until in 1929 a general economic collapse seemed to have finally closed the New World to European migration, the history of Western civilization has been a history of colonization and trade expansion —of a gradual advance westward to the Pacific, southward over Africa and Australasia, and eastward to India and China. Though that movement reached its culmination with the rapid growth of European population in the nineteenth century, it was already well launched by the middle of the seventeenth. Of the total increase of the English stock between 1600 and 1700, one fifth were probably settled on the Atlantic coast of America by the latter date. What does mark the nineteenth century is that it was then that Europe generally first awoke to what had already been the real trend of Western civilization for two centuries. Is it far from the truth to say that the only lasting effect of all the internal wars of Europe from 1618 to 1815 was to keep down the stock which would otherwise have migrated, to ruin the industries which would otherwise have nourished that migration, and to leave to England and Holland the opportunities of American and Asiatic settlement and trade? Alone among all these wars, the long frontier struggle in the east with the Ottoman Empire was fought for a lasting issue.

If this has been the character of the wars of Europe, what has been the character of its peace-making? If one had to give an answer for the whole eighteen hundred years in one rough formula, one would say, I think, the reconciliation of land hunger with culture. That formula does fit, almost exactly, the first nine hundred years. During most of this period, peace-making was largely in the hands of the Christian Church, as the guardian of a faith and a way of life, and as the successor of the Cæsars. To her, territory was a trifle, as culture was, perhaps, a trifle to the barbarian invader; and her peace-making could therefore be a real bargain—the bargain that Walter Scott put in the mouth of Count Witikind:

> "Give me broad lands on the Wear and the Tyne,
> My faith I will leave and I'll cleave unto thine".

That was the basis of the bargain between Pope and Emperor, and it broke down only when, eventually, the two sides of the bargain lost their contrast—when faith became institutionalized by Hildebrand into an *imperium in imperio*, and when, under the feudal system, the Emperor's authority over the broad lands of Europe was reduced to an indistinct overlordship. The resulting conflict of like with like—of two non-territorial universals—admitted of no compromise ; by the end of the thirteenth century it had destroyed both contestants.

During the fourteenth and fifteenth centuries Europe moved slowly towards a new idea : that civilized society is not a single cultural unit within which its members possess territorial rights, but is composed of a number of territorial units, each asserting its own culture. For two centuries the nature of the new territorial units remained in doubt. The Italian city struggled to assert its economic culture against its fellow cities ; the French and English monarchies their new conception of territorial sovereignty and 'civil dominion' ; the Swiss and the Hussites of Bohemia (with very different fortunes) their ideal of democratic independence. It was not until the new sects of the Reformation were forced to seek protectors powerful enough to save them from both persecution and from disintegration that the territorial sovereigns won. The principle *cujus regio, ejus religio* finally identified culture with large territorial units—but, before that principle was fully established, there had been a last attempt to recreate the wider cultural society of the Middle Ages. The empire of Charles V, combining, in the last two years of his rule, the main bulk of Europe with the new colonies of the Spanish Main, had an unequalled opportunity of uniting the whole civilized world in the enjoyment of unimagined natural resources, unprecedented freedom of movement, and the common heritage of the Renaissance—subject only to the compromise of toleration for differing forms of Christian worship. That opportunity was lost in a blind striving after institutional uniformity, and the tragic waste of that futile struggle left the territorial Culture State in undisputed possession of the field.

Since then, for nearly four hundred years, territorial frontiers have remained the staple issue of both war and peacemaking. The Culture State has long outlasted the assumption which originated it : that one State could accommodate within its frontiers only one form of religion. As toleration has taken the place of religious uniformity, the State has substituted new uniformities of its own. In the last hundred years, the consciousness of nationality, the progress of social reform and the growth of industry have combined to multiply the points at which the authority of law and the claims of freedom may conflict and can be reconciled only by like-mindedness between Government and people. So universal has become the identification of culture with nationality, and of nationality with territorial sovereignty, that Britain's sanguine attempt, after the War of 1914–18, to establish a 'Jewish national home' in Palestine, which should be a culture and not a sovereignty, has ended, for the moment, in a despairing proposal for territorial partition.

Until the very end of these four hundred years, however, the organization of the Culture State offered little obstacle to the free movement of the European peoples. The European Culture States, with their high birth-rates, their racial minorities and their political controversies, were glad enough to see their potential unemployed and their potential rebels become citizens of the United States, the British Empire or Brazil. These new overseas nations, on their side, still unhardened to their function as Culture States, were glad enough to give these immigrants work and the opportunity of wealth, in return for no more than a formal salute to the Stars and Stripes or the National Anthem. So the Count Witikind formula was revived as a bargain between the receiving State and the individual, and might, with a little more imagination, have been translated, in the post-War distresses of twenty years ago, into bargains between Governments. Instead of this, the bargain began to break down, much as it had broken down in the Middle Ages. Already, towards the end of the nineteenth century, the German Empire had begun to discourage emigration, and the last twenty years have seen a hardening of European cultural nationalism into that kind of cultural imperialism which demands that the national flag shall follow the emigrant, carrying with it both national culture and national territorial sovereignty. At the same time, the States of the New World began to adopt, not only the policy of deliberate 'assimilation', but also the policy of restricted immigration in the interests of their economic culture ; and, as their economic culture began increasingly to break down, restriction has hardened into prohibition. Cultural nationalism has frozen the peoples of the civilized world into something approaching immobility.

Let us understand clearly what this means. We live in a world of cultural nationalism ; but we have reached a point in the world's history where such nationalism can no longer offer any basis for a lasting European peace, because it can no longer offer freedom of movement to the European peoples. Demands for 'colonies' on the basis of sovereignty can only end, like the irreconcilable claims of Papacy and Empire in the thirteenth century, in the mutual destruction of the claimants and in a period of chaos which will last until some new Renaissance and Reformation bring us a change of mind. *That* is our position in the world's history. Migration is as necessary to-day to the peoples of Europe as it has been at every stage of European history, save when the European stock has been depleted by pestilence and internecine war. The falling birth- and death-rates of northern and western Europe do not materially affect that need; for, while they diminish the number of those who are too young, and increase the number of those who are too old, to work, they leave almost unaltered the proportion of able-bodied producers to dependent consumers. For example, if the present trend of population in Great Britain continues, the age group 20–59, which now constitutes nearly 57 per cent of the total population, will still constitute 55 per cent in 1985. On the other hand, the need for a constant redistribution of population between industrial and primary-producing countries is greater to-day than ever before, by reason of the over-specialization of these two types of economic units.

But the time is utterly and for ever past when the flag can follow the migrant. If he retains his culture, it must be by virtue of its affinity to the general culture of the country to which he migrates. That truth is obvious to the Briton, but it is so far from obvious to the National Socialist and the Fascist that they have staked their all on a policy of cultural nationalism which can lead nowhere but to blind and fruitless war. Until that mood gives place to a sense of reality, and until the real need for freedom of movement can be met by international agreement, Europe will remain in a state of dangerous unrest, and it will be more important that her future frontiers should be strategically defensible than that they should conform exactly to racial or linguistic boundaries.

Though, for the sake of simplicity, I have spoken of migration, it is important to remember that this is an over-simplification. Over the last six hundred years at least, the rise of international commerce has offered a partial alternative to migration, which did not exist in earlier ages; and when, in the nineteenth century, international commerce took increasingly the form of capital exports from Europe for overseas development, it powerfully nourished migration. The overseas assets thus created were European assets, shared by all European nations, even when they were owned principally by a single nation. English investments in the Argentine promoted the migration to that country of harvest labourers from Italy, and so on. But here, too, our economic culture has been frozen into immobility during the last twenty years. Interest on English capital assets in primary-producing countries, brought to England and distributed by taxation, has still relieved the distresses of unemployed Englishmen who could not seek employment by emigration; but it has not been transferable to other nations by the old processes of re-lending and circular trade. In these circumstances, the concentration of such assets in the hands of English investors has had much the same effect on Europe as the unequal distribution of her population in relation to her natural resources. It has damaged the agricultural economy of England and has starved the industrial economy of Central Europe. Under such extraordinary conditions, the direct conversion of sterling debt in Canada, South America and Australasia into mark or lira debt would have been a rational policy. Unfortunately, an international capital levy of this kind was too simple an idea for those who still use the political and economic language of the last two centuries, who still assume that territory is the only asset that one nation can cede to another, and who still think of economic relations in terms of the circuitous self-adjustments of nineteenth century trade and banking.

It is easier for the historian to suggest analogies than to draw conclusions, but the conclusion of this survey is surely plain.

Peace can no longer be made by bartering territories or adjusting tariffs. The Culture State has run its course. It has worked itself out through all its phases—religious, political, linguistic, racial and economic—and it is now becoming that worst of all human things: a conservative anarchy. The problem of peace-making is how to destroy it peacefully; for if it is not destroyed by peace it will be destroyed by war, by the exhaustion of drawn battle or by successful conquest. If by conquest, it will be a barbarian conquest; the Culture State has created no Hellenism, even if it were to produce an Alexander. It has created, instead, the international culture of Marxism—a culture civilized in its origins but barbaric in its effects, whether it take the form of communism or of national socialism.

But it has created one other thing. It has created a British Commonwealth of Nations, now intimately allied with a French Empire, closely related by political and religious tradition to the five small nations of Scandinavia and the Low Countries, and occupying an extraordinary position in the Middle East. This great political partnership possesses vast economic resources which in the nineteenth century promoted the prosperity of all nations and can now be placed more deliberately at their service. Its chief partners have acquired a high degree of technical skill in the handling of these resources; above all, in their exercise of both political and economic power, they acknowledge, dimly no doubt but genuinely, certain standards of moral duty, derived from a common faith and a common way of life. The wheel of history has not turned full-circle—perhaps it never does ; but it has brought back to us something like the same opportunity as was offered four hundred years ago to the empire of Charles V, the opportunity of embracing diverse territorial sovereignties and races, diverse religious and political creeds, in a wider community, where all men can, at least, find a growing freedom of access both to spiritual and to material wealth. That opportunity may, all too easily, be lost once more—lost in the particularist selfishness of the Culture State or in a blind striving again after the institutional uniformities of a League of Nations or a Federal Union. But if it is lost, we shall be more guilty than Charles V or Philip II, for now the swing of the wheel is with us. It is moving away from, not towards, the Culture State ; it is moving towards, not away from, the greater Culture Society.

Our success or failure will depend mainly on the shrewdness with which we judge what really matters in civilization—what is unimportant enough to be surrendered, and what is valuable enough to be purchased. The civilized man always gets the best of his bargains, not because he has the greater power of compulsion or persuasion, but because he has outgrown his taste for toys and does not mind parting with them—whether he is the trader bartering glass beads for rubber, or the medieval churchman granting land in exchange for repentance. Our danger is that so many trifles have still a superstitious value to one section or other of our democratic electorates : to the nationalist, mere territory ; to the capitalist, his overseas investments ; to the trade unionist, his control of the labour market by restriction of apprenticeship and prohibition of immigration. After the War such problems cannot, of course, be solved by an abrupt abolition of controls and an unconsidered return to freedom. In many of the most important spheres of economic policy, freedom is, indeed, meaningless ; free access to raw materials may mean only freedom to covet them if the purchaser cannot find enough foreign exchange to buy them in sufficient quantities. Nationally, there may be legitimate differences of opinion as to the scope and merits of economic planning ; but internationally we have already a misplanned economy, which must be deliberately replanned if it is not to lapse into chaos. The question for us is whether, in approaching this task, labour and capital in all the democracies of the British Commonwealth can so free themselves from old vested superstitions as to give the necessary discretion for replanning, and the necessary mandate for mutual help and toleration, to international bodies.

That, at least, is one of the two questions that we have to prepare ourselves now to answer—now, above all, when our old toys look so small in the setting of life and death. The other is a greater question still, but I can do no more than mention it. It is the other side of the peace bargain. Having decided what is unimportant enough to be surrendered, what is it that is valuable enough to be purchased at this price ? For the sacrifice will be real, even though it will be mainly a sacrifice of prejudices. What are we to ask in exchange ?

Simply, I think, the recognition of one fact, which we ourselves have almost ceased consciously to recognize. All European civilization for sixteen hundred years has been based on one fundamental assumption : that State law must conform to moral standards which it cannot itself originate. These standards are the measure both of the powers of government and of the duties of citizenship. They are so absolute that their authority has been most accurately described in terms of revelation. But it is of the essence of this conception of civilization that these absolute standards are primarily standards, not for the State, but for the individual. Absolute as they are, every application of them to organized social action involves some compromise, and this debatable land of compromise has been, throughout European history, the scene of all the conflicts and entanglements of Church and State. On this paradox the whole fabric of our civilization rests. Democracy, in the only real sense of that word, is simply the extreme assertion of it—the claim that any exercise of political power must be measured by the individual citizen's sense of right and wrong, even though that measure must always be, to some extent, incompatible with the most efficient exercise of such power. Every effort to evolve a special political morality on the basis of 'reason of State', 'natural law', the 'rights of man' or the rights of nations, has ended in disaster, as it is ending in disaster to-day.

In other words, every conception of government ever formed by Europeans, but above all the conception of democracy, assumes the social recognition of a personal religion, and is meaningless without that assumption. To convert that assumption into the conscious and deliberate assertion of a faith is the other, and greater, half of peace-making. If we are to make peace by merging the Culture State in a wider union, the only possible name for that union is Christendom, and its success or failure will depend on its convinced acceptance of the essential implications of that name.

WORK OF THE MEDICAL RESEARCH COUNCIL

THE recently issued report of the Medical Research Council for the year October 1, 1938–September 30, 1939*, covers a period of some difficulty owing to the disturbed condition of world politics, culminating in the outbreak of war. Nevertheless, a perusal of the report suggests that the progress of the research work pursued under the Council suffered little, if at all, from the state of war expectancy, except for some readjustments towards the close of the Council's year.

With regard to special war emergency services, the Council undertook the organization and supply of antitoxins, in particular tetanus and gas-gangrene antitoxins, that might be required for war casualties, and sera and vaccines that might be needed in dealing with outbreaks of epidemic disease. The organization of an emergency laboratory service and of depots in the Home Counties for the collection, storage and supply of blood for transfusion purposes was also undertaken, and the Council frequently advised many Government departments which sought its assistance.

Nutrition in time of war, both as affecting the population as a whole under conditions of rationing, and the armed forces in respect of the great use of tinned foodstuffs in Service rations, were also the subject of investigation by the Council's staff. Government departments sought the assistance of the Council and of its Industrial Health Research Board on problems of industrial health, particularly in the production of war material, and special war problems are in course of investigation, such as shock occurring after serious wounds, sepsis complicating war wounds and physiological problems of aviation.

Passing to investigations on more general medical problems, a Committee on Preventive Medicine has studied methods of immunization against diseases such as diphtheria and whooping-cough with the view of evaluating their efficiency and determining the best technique, and has inquired into the problem of cross-infection in hospital wards. The causes of the high mortality rates due to broncho-pneumonia, to enteritis in children, and to respiratory diseases during winter have also been investigated.

The chemistry of brain reactions has been the subject of much research, and one of the facts established is the key position held by glucose as the main fuel of nerve tissue. It is also well established that substances normally present in the body perform specific functions in relation to the nervous system. In this connexion, Sir Charles Martin, Dr. Harriette Chick and their colleagues, working at Cambridge, have shown that when pigs are reared on a diet deficient in vitamin B_6 they suffer from epileptic fits similar to those occurring in human epilepsy, and that when this vitamin is then added to the diet the fits cease. Prof. R. A. Peters and his colleagues at Oxford have likewise shown that when vitamin B_1 is deficient in the diet, both man and animals develop characteristic abnormalities of the nervous system. It was shown that, in the absence of this vitamin, the brain cells cannot make proper use of glucose as a food.

At the National Institute for Medical Research, Hampstead and Mill Hill, Dr. Stuart-Harris, Dr. Andrewes and Dr. Wilson Smith have conducted studies upon influenza. An epidemic occurred in the early part of 1939 which clinically resembled influenza, and attempts were made to isolate the influenza virus, which has a characteristic property in being transmissible to ferrets. Even with material from typical cases, all attempts to transmit a virus infection to ferrets failed, and only seven throat washings of patients, out of fifty-nine tested, yielded virus infective for ferrets. The outbreak, as a whole, appears to have been one in which the known influenza virus played a subordinate part, suggesting that other virus strains are capable of causing influenza-like attacks. Drs. Andrewes and Wilson Smith have also continued their experimental inquiry into the factors influencing the immunizing effect of the influenza vaccine.

The relation between human leprosy and rat leprosy was the subject of an interesting research by the late Sir Patrick Laidlaw. The rat disease, caused by an organism very similar to the human leprosy bacillus, is readily transmitted from rat to rat, but there is only one record of the successful transmission of human leprosy to the rat. Syrian hamsters, found by Adler of Jerusalem to be susceptible to infection with the human leprosy bacillus, were inoculated with human leprosy material, and one of the animals developed an infection with typical bacilli. With this material Sir Patrick Laidlaw found it easy to transmit infection not only to hamsters but also to white rats. A critical investigation by Sir Patrick suggested that the original material was derived from a case of human infection with the rat organism and not with the organism of human leprosy. The suggestion is made that human leprosy in the past may have arisen from the rat disease, the bacilli afterwards losing their infectivity for the rat with adaptation to the human tissues.

* Report of the Medical Research Council for the Year 1938–1939. (H.M. Stationery Office, 1940.) 3s. net.

Work on biological standards, under the direction of Dr. Hartley, is also conducted at the National Institute, and various standards already established are maintained there. A British standard for a gas-gangrene antitoxin (*histolyticus*) has now been made available, and the British standard for diphtheria antitoxin has been placed on regular issue. Much work has also been done on the standardization of tuberculin, various other antitoxins, vitamins and insulin. The work of producing, standardizing and distributing bacterial suspensions and sera for diagnostic purposes has been continued at the Standards Laboratory, Oxford.

The work of clinical research units, of external staffs, wholly or partly financed by the Council, and of individual research workers receiving grants, are summarized in the report, and many valuable contributions have been made to medical knowledge.

It is the intention to move the National Institute at Hampstead to Mill Hill, in association with the Farm Laboratories there, but this has been delayed by the war emergency. Some of the ancillary buildings are, however, ready for occupation, and the shell of the main building is nearing completion.

OBITUARIES

Prof. J. H. Michell, F.R.S.

THE death on February 3 of Prof. J. H. Michell, at the age of seventy-six, is a severe loss to Australia, and the great value of his work both as mathematician and teacher cannot be easily overestimated. His modesty was such that proper appreciation of his real worth was often confined to the fortunate few who were in close contact with him, either through his undergraduate lectures or some research problem.

After an early education in Melbourne, Michell proceeded to Cambridge, where his performance at the Mathematical Tripos and afterwards led to his early election as a fellow of Trinity College. Here he devoted himself to research in elasticity and hydrodynamics, and a remarkable number of important papers in both subjects resulted. He was largely responsible for the introduction of stress equations of equilibrium of an elastic solid which did not involve explicit introduction of the displacement-equations and provided a formal solution of the equations for an isotropic solid with a plane face under given surface tractions. The important theory of that type of deformation known as dislocation was first developed by Michell and he was also one of the first to make use of inversion in solving problems of plane strain and the bending of plates. His work in elasticity included very valuable discussions of the general theory of bending of beams and plates under various loads, besides the detailed solution of a number of special problems such as the elastic equilibrium of conical bodies, the calculation of strains due to concentrated loads, the deformation of naturally curved rods, etc. On the dynamical side of the subject Michell was responsible for the theory of the vibrations of a helical rod and of a circular ring. Perhaps his most interesting contribution to hydrodynamics is the theory of the 'highest' wave in water, but he also published work on discontinuous fluid motion and on wave resistance to ships.

As a just recognition of this excellent work, Michell was elected a fellow of the Royal Society in 1902. A few years later he was appointed lecturer in mathematics in the University of Melbourne and began a long career of devotion to the teaching of the subject. In 1923 he was appointed professor of mathematics and his influence became still more pronounced. To his honours students, among whom I had the privilege to be numbered, Michell was the very personification of mathematical erudition. An hour's lecture by him was an intellectual treat and a whole course of lectures something to look forward to with keen anticipation.

Michell was a great exponent of vector methods and was remarkably facile in their manipulation. He was undoubtedly one of the few mathematicians of his time who really thought in terms of vectors, and he was at pains to educate his students also to think in this way, which is, after all, the natural one for mathematical physics. His influence in spreading a proper appreciation of vector methods represents alone a very important contribution to applied mathematics.

When Michell retired from his chair in 1928 his valuable services were partly retained as honorary research professor. Despite the heavy calls on his time from his academic duties, Michell kept well abreast of all developments in his special subjects and gave several courses of lectures on modern hydrodynamics after his retirement. In 1937 he also published, with his colleague, Mr. M. H. Belz, a treatise on the elements of analysis which is an excellent illustration of the combination of vigour and clarity which characterized his approach to all mathematical problems.

Prof. Michell's modesty and good nature, combined with his remarkable intellectual qualities and willingness to assist in the smoothing-out of difficulties, however trivial, endeared him to his students, all of whom will remember him with affection and admiration.

H. S. W. MASSEY.

Prof. Otto Toeplitz

Prof. Otto Toeplitz, who died on March 15 in Jerusalem, was one of that rare type of scholars who combine with a high standard of specialized research a deep interest in the history of their science and its bearing on general questions. Toeplitz, born at Breslau in 1881, studied mathematics in Breslau and Berlin, became *Privatdozent* at Göttingen in 1907, professor of mathematics at Kiel in 1920 and at Bonn in 1928. In 1935 he was dismissed in consequence of the racial laws of the Nazi Government and went in 1939 to Palestine as scientific adviser to the administration of the Hebrew University.

Toeplitz's mathematical interest was wide and covered all branches of research, but was deeply rooted in algebra. He liked to consider analysis as an algebra of an infinite number of variables, an example of which was given by Hilbert's treatment of integral equations as special cases of linear equations and quadratic forms of infinite sets of variables. Most of his papers deal with problems of this type—infinite matrices and the corresponding bilinear and quadratic forms. His great knowledge and thorough insight in this subject is testified by the article on integral equations in the "Mathematical Encyclopædia" (1928) written in collaboration with E. Hellinger. But Toeplitz's general attitude to mathematics, which he preferred to consider more as an art than as a science, is more clearly visible in his quasi-popular book "Von Zahlen und Figuren", written with Rademacher in 1930, which seems to me a masterpiece of that class of scientific literature which attempts to instruct a wider public in the fundamental ideas of science. It is not easy, but certainly fascinating reading.

In later years Toeplitz's interest went more and more to the history of mathematics. He was a classical scholar able to read Greek texts and he knew his Plato just as well as his Gauss and Weierstrass. Together with Neugebauer and Stenzel, he founded the periodical *Quellen und Studien zur Geschichte der Mathematik, Astronomie und Physik*, to which he contributed several articles, chiefly concerned with mathematical ideas in Plato's work.

Toeplitz had no intimate relation to physics, but had nevertheless some indirect influence in its development, the present writer being the link. As a student in Breslau, I was much under the influence of Toeplitz, who was my senior by one year, and though my interest in algebra was not great he insisted on my learning matrix calculus properly and occasionally refreshed my knowledge when we were together again as young teachers in Göttingen. This turned out to be a great advantage to me, first in developing Minkowski's form of relativity, then for the study of vibrations in crystals, which are determined, indeed, by a quadratic form of a (practically) infinite number of variables, but decidedly at the birth of quantum mechanics. When Heisenberg expressed the relations between the quantized amplitudes of atomic vibrations as a kind of symbolic product, the recollection of Toeplitz's instructions enabled me to recognize them as matrix products and (with Jordan) to work out the principal features of quantum mechanics. Though this is only a purely formal step beyond Heisenberg's idea it is perhaps not quite trivial, as shown by the fact that Dirac, in independently developing Heisenberg's idea, invented a new formalism, his q-number calculus, without immediately recognizing the identity of Heisenberg's process with matrix products. Toeplitz himself regarded this unexpected application of his beloved matrices with some suspicion, and rightly from the point of view of the conscientious rigorous mathematician. But he nevertheless continued to give me his advice on special questions.

Toeplitz was devoted to teaching and spent much time and work on it. He was a faithful friend, a man of extreme kindness, but also of strong character and courage. This he amply proved during the hard years of Nazi rule, when he worked with all his force on the problem of saving young non-Aryans from Nazi persecution. M. Born.

Prof. Alexandre Besredka

The recent death of Prof. A. Besredka at the age of seventy deprives France of yet another member of that sadly diminished group of scientific workers whose names are associated with the brilliant and provocative work produced in the early days of the Pasteur Institute. The mention of Besredka's name immediately evokes the whole conception of local as opposed to general or humoral immunity; a conception which has given rise to considerable controversy and thus provoked much fruitful experimental work on the nature of inflammation and the reaction of the body to infection. No memoir would, however, be complete which failed to pay tribute to Besredka's pioneer work in many fields of bacteriology and immunology. During his early days in Paris he was assistant to Metchnikoff. He applied the methods of this master to an illuminating study of the reaction of phagocytes to bacterial exotoxins and endotoxins and to the injection of mineral poisons. Later, Besredka made important contributions to the development of specific immunization against infection, notably in his studies on streptolysin and the use of sensitized vaccines. Anaphylactic shock, which is an abnormal and sometimes disastrous immune response to the injection of foreign protein, also claimed Besredka's attention.

The later years of Besredka's life were devoted to the study of local immunity to infection. He believed that immunity depends upon a state of resistance residing locally in those tissues that are attacked by an infection, and denied the importance of the general immune response of the body and the antibodies circulating in the blood stream. According to Besredka, all attempts at immunization should be applied locally to the susceptible tissue and should aim at modifying the reaction to the noxious agent. His experimental work was mainly confined to infections of the skin, such as anthrax and the staphylococcus, and to intestinal infections, such as typhoid and dysentery. In order to obtain immunity to skin infections Besredka advocated intracutaneous vaccination, inunction or the application of poultices containing the products of bacterial metabolism. It is true that the local resistance of the skin can be raised by these measures, but there is considerable evidence that a similar result can be obtained by non-specific stimulation and that, apart from any question of a general immune response to these procedures, the increased resistance to infection may be due to a non-specific inflammatory response.

In order to combat intestinal infections Besredka advocated the oral administration of bacterial vaccines combined with bile to increase the permeability of the intestinal mucosa. These vaccines have been extensively used in France; but it is difficult to express any final verdict on their efficacy, or to disentangle the local protective effect from the part played by the serum-antibodies which are undoubtedly produced.

If the contribution of a man of science can be measured not only by those discoveries or 'lucky shots' which command universal and immediate acceptance, but also by the skilful presentation of ideas which lead to original experimental work and to the exploration of fresh avenues of approach to intricate problems, then Besredka should be assured of an eminent place in the calendar of bacteriologists.

We regret to announce the following deaths:

Prof. Heinrich Bonhoff, formerly professor of hygiene in the University of Marburg, aged seventy-six

Prof. G. Gallerani, emeritus professor of physiology in the University of Carnerino, aged seventy-six.

Prof. V. I. Sihvonen, professor of chemistry in the University of Helsinki, killed in an air raid on November 30.

NEWS AND VIEWS

Education in the Royal Air Force

IN NATURE of April 6, p. 526, we discussed at some length the urgent case for the provision of adequate educational services by the departments responsible for the Armed Forces. This discussion was mainly in terms of Army organization. The War Office, however, was not alone in showing a lack of regard for educational matters. The general education scheme of the Air Force, which had been carefully built up over many years, seems to have been virtually scrapped overnight on the outbreak of the War—the educational staff dispersed and the premises appropriated to other purposes. Even in the R.A.F. schools of technical training, of which the educational branch has been an essential component, there appears to have been a noticeable educational set-back. This is surely evidence of a regrettable failure to give educational values their proper place in a modern fighting service, manned (as the Air Force conspicuously is) by the finest types of young men the nation possesses. In the treatment meted out by the Air Ministry to its educational staff—the great majority of whom are officers with considerable scientific or technical qualifications—there is further indication of an unfortunate attitude towards education. The civilian status which these educational officers have hitherto had has always made their task an extremely onerous one. For, disregarding the experience of the Navy and the Army—the officers of the education branches of which are commissioned officers on the same footing as executive officers, medical officers and so on—the Air Ministry has continued to impose a civilian status on its educational staff.

Nevertheless, we understand that, before the outbreak of the War, it was accepted by the Air Ministry that whilst this arrangement might be adhered to in peace, it could not work under 'active service' conditions. The education officers were invited to accept commissions in the Royal Air Force Volunteer Reserve, under definite conditions as to pay, rank, promotion, etc. In accordance with this scheme, all educational posts to be retained on the outbreak of war were ranked and education officers were earmarked to fill them. Uniform allowances were granted and all other necessary arrangements were made to enable the scheme to work as smoothly as possible if and when hostilities should begin. In this way, at the beginning of last September, the Air Force education officers assumed their new status. Without warning, however, education officers were informed a few months later that they had been demobilized and must revert to civilian status. That the Air Ministry now realizes something of the invidious position in which this decision has placed its education officers may be inferred from an instruction recently issued that the education officers are to wear uniform as Air Force officers notwithstanding that they have been demobilized and are no longer technically on 'active service'.

The Air Council should see to it that this state of affairs is put right without delay. The reason given for demobilizing the education officers was, we believe, that some (but by no means all) of them were receiving emoluments as Air Force officers greater than those they had received as civilians before the War—though the extent to which this would happen must surely have been known to the Air Ministry when the conditions of the scheme were drawn up. In any event, on any reasonable basis of computation, the sum involved is a mere trifle. Probably it could be eliminated entirely by an adjustment of ranks (and perhaps by other means) acceptable to the education officers, without prejudicing the Air Force status of these officers as has been done by the ill-advised steps recently taken.

The British Association

THE British Association intends, unless unforeseen events intervene, to hold a conference in the University of Reading, by kind permission of the Council of the University, during July 25–27. The general reference will be to science in national and international aspects, and Sir Richard Gregory, president of the Association, will open the conference as chairman. Thereafter there will be meetings in four groups, dealing respectively with international intellectual co-operation; natural resources and national needs; social aspects of human nutrition; and scientific discovery and progressive industry. The preliminary programme for the conference is taking shape, and already a number of distinguished speakers have consented to participate, if circumstances permit, in the various group-discussions. The programme should be ready for issue in the early part of next month. Considerations of finance and the restriction of paper supplies will prohibit its distribution on the usual extensive scale, and any interested persons who do not receive it by the middle of May are requested to ask for it to be sent from the office of the Association at Burlington House, London, W.1.

Admission to the conference will be by tickets, the number of which will be restricted to some seven hundred by the available accommodation. The tickets will be free, but members of the Association will be urged to maintain their subscriptions, and others will be invited either to become members or to contribute by donation to the funds of the Association. Arrangements for the lodging of visitors in the University halls of residence are in hand. The Council of the University will hold an informal evening conversazione for members of the Association and guests.

Siméon Denis Poisson, For.Mem.R.S. (1781-1840)

ON April 25, 1840, the distinguished mathematician Siméon Denis Poisson died at Sceaux at the comparatively early age of fifty-eight. Born at Pithiviers on June 21, 1871, he was the son of a soldier who had served in the Seven Years War, but was brought up by an uncle at Fontainebleau. At the local school he attracted attention by his gift for mathematics, and at the age of seventeen gained admittance to the École Polytechnique, with which he remained connected for practically all the rest of his life. In 1800 he presented to the Paris Academy of Sciences his first mathematical memoir, gaining thereby the interest of Lacroix and Legendre. He was appointed to the chair of analytical mechanics in the École Polytechnique, held the chair of mechanics in the Faculty of Sciences of Paris, was given a seat on Bureau des Longitudes, and became an examiner to both the École Polytechnique and the École d'Artillerie at Metz.

Altogether Poisson wrote more than three hundred memoirs on mathematical, astronomical and physical subjects. His most notable book was his "Traité de Mécanique", published in two volumes in 1811. His work on capillary attraction appeared in 1831 and that on the mathematical theory of heat in 1833. A man of deep convictions, he took no part in political life; finding in mathematical pursuits his work and recreation. When enjoined to spare himself, his reply was "La vie c'est le travail". Among a great number of remarkably able men of science, he stood out as one of the foremost. He was buried in Paris, and a memorial notice was afterwards written by Arago. Napoleon had raised him to the rank of baron, and a few years before his death he was made a peer of France.

Sir Thomas Clouston (1840-1915)

SIR THOMAS SMITH CLOUSTON, a leading Edinburgh psychiatrist, was born on April 22, 1840, at Nist House, Orkney. He was educated first at Aberdeen Grammar School and then at the University of Edinburgh under Goodsir, Syme, Simpson and Laycock. He graduated M.D. in 1861, when he received a gold medal for his thesis on the nervous system of the lobster. After serving four years as assistant physician to the Morningside Asylum, Edinburgh, he was appointed medical superintendent of the Cumberland and Westmorland asylum at Carlisle, where he remained until 1873, when he succeeded Skae as medical superintendent at Morningside and continued in this post until his retirement in 1908. During his period of office he carried out many reforms in the asylum, including rebuilding and the introduction of humane and efficient methods in the treatment of the patients, in addition to making a large number of clinical and pathological observations. Besides being in great demand as a consultant not only in mental disease but also as an expert in forensic medicine, Clouston took an active part in municipal affairs at Edinburgh.

In addition to his principal work entitled "Clinical Lectures on Mental Diseases", which went through six editions between 1883 and 1904 and was for many years a standard text-book, Clouston was the author of "Neuroses of Development", which formed the Morison Lectures for 1890, "Hygiene of Mind" (1906) and "Unsoundness of Mind" (1911). He also contributed an important article on "The Epochal Insanities" to Allbutt's "System of Medicine" (1899). He was the recipient of many honours. In 1911 he was knighted, in 1907 he was made Hon. D.C.L. of Aberdeen and in 1911 of Edinburgh. He was also president of the Medico-Psychological Association of Great Britain and Ireland, of which he was one of the founders, and of the Royal College of Physicians of Edinburgh, and editor of the *Journal of Medical Science*. He died on April 17, 1915.

Factory Hours for Women and Young Persons

A REPORT on hours of employment of women and young persons in factories during the first five months of the War, issued by the Home Office (Cmd. 6182. London : H.M.S.O.), reviews the experience of 1914–18 and the situation at the outbreak of war. It was necessary to agree freely to substantial overtime at the outset so as to meet immediate difficulties and afford time, without holding up urgent supplies, for inquiries into the actual needs of the case. It is also essential, however, to make clear to employers and workpeople that the Factories Act has not gone by the board, and that hours must be regulated, through its machinery, in accordance with a considered policy. The policy was pursued of reviewing the position at individual factories at fairly short intervals, especially during the first months of the War. Orders authorizing extended hours have been made in respect of 2,459 factories, but the hours authorized were often shorter than those applied for, and some applications were refused altogether. Many factory occupiers to whom orders were granted in September and October allowing 57 hours for women have been able to maintain the necessary output with fewer working hours by means of reorganization, and in 239 cases on expiry of the order the occupiers have not desired renewal. A system of two day-shifts has been authorized for 299 factories, but applications to employ women at night have been relatively few and confined almost entirely to armament or allied factories; altogether 57 such orders have been made.

Orders have been made for thirty factories allowing the employment of male young persons more than sixteen years of age in a system of two day- and night-shifts or three eight-hour shifts. In the early weeks of the War many firms, particularly in the engineering industry, and firms engaged in making blinds and other articles urgently required owing to lighting restrictions, were permitted to employ young persons less than sixteen years old up to 47 or 48 hours a week for a short period, rarely longer than two months. Many factory occupiers took such effective measures during the period of the concession that when their orders expired it was unnecessary to employ these young persons beyond the statutory maximum of 44 hours. During the early months of the War, short-term orders permitting the employment of young persons under sixteen up to 48 hours a week were granted to 439 factories, of which 302 were engaged in general engineering and 48 in shipbuilding and marine engineering; 312 of these orders were not renewed, but at the end of the five months under review 133 such orders were in operation. The report states that it is the policy of the Government not to authorize hours which in the light of experience and of scientific investigation are detrimental to health or efficiency.

The Higher School Certificate Examination

THE Higher School Certificate Examination, about which there has recently been an investigation, has two functions: to provide a test of sixth form work and to help in the selection of State and local Education Authority scholars. For the latter purpose the investigators recently appointed to investigate the position of these examinations suggest that they are less suitable than the examinations for open scholarships at the universities, and they also say that the work of non-scholarship candidates is cramped by their association with the others. Yet they found that the examination achieves its double purpose with a fair measure of success and they have not recommended drastic changes. Points for and against two alternative proposals are discussed in a report recently issued (The Higher School Certificate Examination: being the Report of the Panel of Investigators appointed by the Secondary School Examinations Council to enquire into the Eight Approved Higher School Certificate Examinations held in the Summer of 1937. Pp. 93. London: H.M. Stationery Office, 1939. 1*s*. 6*d*. net). The first is that the task of recommending candidates for the award of State scholarships might be handed over to the universities. The second alternative is that the examination might be divided into two parts, one of which would serve for awards of certificates and as a qualifying test for candidates for scholarships, and the other would be entirely competitive. The competition itself would then be conducted by a new central examining body.

The investigators found that the regulations tended both to enrich the larger examining bodies and to impoverish the modern universities, and they have made a simple proposal about the distribution of scholarships which is designed to correct these tendencies. Although the investigators have stated the facts and explained the difficulties clearly, the report seems inconclusive in many respects. It may be no worse for that, yet it is all the more disquieting on nearing the end of the report to find four pages of almost unrelieved condemnation of the science syllabuses and papers, and by implication of the work of the science sixth forms in schools. It is impossible fairly to summarize the statements made on these concisely written pages, but the gist of the matter is that the training of these candidates is too remote from the ordinary affairs of life, that the humanistic and cultural aspects of science generally receive scant attention, and that pupils are not helped to realize how closely scientific discoveries affect human progress or their own life and work. Severe criticism of this sort calls for some response, and the first step towards reform is that those who are engaged in the teaching and examining of science at the Higher School Certificate stage should read this report in a spirit of self-examination. If they do so it is probable that only the unimaginative will award themselves very high marks for their work.

A Pioneer Wireless Station

A MEMORIAL stone in grey Cornish granite has been erected at Alum Bay in the Isle of Wight to mark the position occupied by the first permanent wireless station. The Needles Wireless Telegraph Station holds a place of honour in the history of wireless communication because it was here, in 1897, after a few experiments on Salisbury Plain and other places, that Marconi and the engineers of Marconi's Wireless Telegraph Co. carried out experiments which led to the great achievement of spanning the Atlantic by wireless from Poldhu in 1901. It is claimed that the Needles Station was the first from which a paid marconigram was transmitted on June 3, 1898. The working of this Station was inspected by many prominent people, among them being Lord Tennyson and Lord Kelvin.

The first two paid wireless messages ever dispatched were sent by Lord Kelvin, one to Sir William Preece at the General Post Office on June 3, 1898, and the other to Sir George Stokes, the Cambridge physicist. Lord Kelvin insisted on paying for the messages as an indication of his belief in the possibilities of wireless communication at a time when there was much scepticism. A photograph of the memorial to Marconi on the cliffs of Alum Bay appears in *The Times* of April 11. Four bronze plaques are attached to the memorial; one pays tribute to "Marconi and his collaborators, who carried out from Dec. 6, 1897, to May 26, 1900, a series of experiments which constituted some of the most important phases of their early pioneer work in the development of wireless communication of all kinds". Another records the production of the *Transatlantic Times* in 1899, the first newspaper to be produced at sea, which received information by wireless telegraphy from the Needles Station and printed it in the United States liner *St. Paul.*

Croydon Natural History and Scientific Society

It was on April 6, 1870, that the Croydon Microscopic Club, the forerunner of the Croydon Natural History and Scientific Society, held its inaugural meeting, so the Society is practically a contemporary of NATURE. According to the early records, about a hundred and fifty were present at the meeting, "not all of the savantissime school, it is true—but the majority evincing an earnest desire for the pursuit of science in one of its most interesting branches". Microscopical demonstrations were arranged. The chair was taken by Mr. H. Lee, who reported that the Club included three fellows of the Royal Society, four of the Linnean Society, three of the Geological Society (one of whom was treasurer of the Club), and several members of the Royal Microscopical Society and the Quekett Microscopical Club. Among the speakers were Frank Buckland and Dr. J. S. Bowerbank, F.R.S.

Further meetings were held during 1870. On May 4, J. W. Flower read a paper on the microscopical organisms of the flints. On May 14, the Club formed a party with members of the Quekett to explore the River Wandle for freshwater organisms. The quest was apparently not very successful, but mention is made of the fact that the party managed to obtain adequate refreshment of bacon and eggs, cold beef, tea, etc., at the "Greyhound". On May 28, the Club visited the house and grounds, at Park Hill, of Mr. Flower, who "had provided 2 cart loads of Flints for them to crack" in search of fossil foraminifera, etc.; "the popping of champagne corks was frequently heard above the sound of the geological hammers". On July 30, Mr. H. W. Peek, M.P., entertained the Club, and on November 30, the Club's first soirée, with exhibits, was held in the Public Hall, Croydon. Lest it be thought that undue prominence was given to refreshment of the body rather than the mind, we hasten to add that the Croydon Natural History and Scientific Society, the honorary secretary of which is Capt. B. V. Pring, 33 The Windings, Sanderstead, Surrey, has a distinguished scientific record and normally holds regular meetings twice a month at the Central Library, Croydon.

Bacteriological Warfare

In his inaugural thesis (*Thèse de Paris* 1940, No. 19) on the experimental production of epidemics and epizootics, Dr. Ernest Sarfati states that the question of bacteriological warfare formed the subject of an inquiry in 1923 by a committee of experts including Profs. Bordet of Brussels, Cannon of Harvard, Madsen of Copenhagen, and Pfeiffer of Leipzig. As the result of the inquiry a protocol was issued at Geneva on June 17, 1925, signed by representatives of Germany, the United States, Great Britain, France, Italy, and about forty other nations who undertook that their countries would not take part in bacteriological warfare, the possibility and dangers of which they fully recognized. The experts classified the mode of transmission of bacteria into an enemy country as follows: (1) transportation by aircraft or spies; (2) dispersal of microbic cultures in liquid or solid form; (3) transmission by intermediate hosts such as rats or lice, or the poisoning of projectiles or steel weapons.

The epidemics which theoretically might be produced artificially by these means include malaria, yellow fever, bacillary dysentery, diphtheria, typhus, plague, cholera, enteric fever, Malta fever, tuberculosis, smallpox, influenza, rabies, poliomyelitis and epidemic encephalitis, while the principal epizootics would be glanders, anthrax, foot-and-mouth disease, peri-pneumonia of cattle, and pernicious anæmia of horses. Special circumstances, however, are required to produce epidemics and epizootics, and attempts have repeatedly been made to destroy certain animal species, particularly locusts, without success. Dr. Sarfati comes to the conclusion that while bacteriological warfare is not impossible, it would only succeed in strictly localized areas, in which case the ordinary methods of prophylaxis, including the use of serums and vaccines, would prevent the spread of infection.

Sir Leonard Woolley and Indian Archæological Studies

As anticipated, the reception accorded by Indian opinion to Sir Leonard Woolley's report on the Archæological Department and the state of archæological research in India can only be described as mixed. To a great extent, criticism of its findings has been inspired by umbrage taken that his expert advice should have been invited by the authorities and his verdict received and published, without sufficient regard being paid to the views and opinions of those among the Indians themselves considered competent to judge. Thus it may be considered that it was to some extent a reaction against any attempt on the part of the Government to restrict existing archæological activities in the field that was responsible for the resolution of the Archaic and

Cultural Section of the Indian History Congress, which met at Calcutta on December 15–17, 1939, requesting the Government of India to reconsider the decision to stop further excavation work on account of financial stringency due to the War. A little discrimination in the terms of the resolution would have been indicative of a juster sense of proportion.

A less partial, though not entirely unbiased, view of the situation in archæological studies under official control is taken in an analysis of Sir Leonard Woolley's report, which appears in *Science and Culture* (Calcutta) of January and February 1940. In summarizing his views on the recommendations, the author characterizes the proposals as to museum management, the use of museums for educational purposes, on the training of officers, long-period budgets, choice of sites for excavation, and co-operation between the department and educational institutions as being "very sound", and holds that they should be given immediate effect. At the same time he claims that they are neither new nor original, and suggests that the attacks on the work of the Archæological Survey, excepting those relating to excavation and exploration, are largely unjustified and irrelevant, "probably due to his ignorance of Indian archæology and the methods and practices of service followed by the Government of India". Sir Leonard needs no defender. To refute such charges, as well as much of the criticism to which it is not possible to refer here, it is unnecessary to go outside the pages of the report itself. Such views, however, if general, would not augur well for the future of scientific archæology in India.

The National Physical Laboratory

A NEW Department of Light has been formed at the National Physical Laboratory, to comprise the former Optics Division of the Physics Department and the Photometry Division of the Electricity Department. Mr. T. Smith, head of the Optics Division, has been appointed superintendent of the new department as from April 1, 1940. Dr. E. H. Rayner retired from the post of superintendent of the Electricity Department on March 31, 1940, having attained the normal age limit. He has been succeeded by Mr. R. S. J. Spilsbury, formerly principal scientific officer in the Department.

Recent Earthquake Recordings

ACCORDING to a *Times* message, earth tremors were felt on April 12 on the south coast of Newfoundland at the settlements of François and Rencontre. No damage is reported. The earthquake of November 18, 1929, was felt in the same region though the greatest damage was done to submarine cables somewhat to the south, that is, between lat. 44° N. and 45° N. and between long. 55° W. and 57° W. (NATURE, 124, 859; 1939: 127, 609; 1931).

During March, sixteen earthquakes were registered at Kew Observatory, the greatest number on any one day being two on March 28. Most of the earthquakes registered were small, and there appears to have been a good deal of disturbance due to microseisms. The greatest shock recorded was also on March 28 at 16h. 2m. 4s. G.M.T.

At the Dutch Observatory at De Bilt prominent earthquake shocks were registered on March 27 and 28. The former was apparently not registered at Kew, but the latter may have been the one showing the greatest amplitudes of the month at Kew. Dr. G. van Dyk is of the opinion that the P waves arrived at De Bilt at 16h. 1m. 57s. G.M.T. and the S waves at 16h. 12m. 5s. G.M.T., giving an epicentral distance from De Bilt of approximately 84·2°, assuming a normal depth of focus.

Announcements

THE following recent appointments and promotions in the Colonial Service have recently been made: E. O. Longley, veterinary research officer, Nigeria; A. B. S. Boswell, assistant conservator of forests, conservator of forests, Malaya; W. J. Eggeling, assistant conservator of forests, senior assistant conservator of forests, Uganda.

THE World Congress of Faiths will hold its fifth annual meeting at Bedford College, University of London, during July 5–10. The Marquis of Zetland, Secretary of State for India, will preside at the inaugural meeting at 5 p.m. on July 5. The main theme for the Congress will be "The Common Spiritual Basis for International Order". Further information can be obtained from the Secretary, Mr. Arthur Jackman, Room 336, Abbey House, 2–8 Victoria Street, London, S.W.1.

A MEDICAL building belonging to the Hebrew University has recently been completed in the Garden of Olives in Jerusalem. It will serve as a medical centre for diseases of all kinds, not only for Palestine but also for the rest of the Near East.

OWING to the need for economy in the use of paper, the Council of the Royal Sanitary Institute has decided that after the completion of the present volume in June, the *Journal of the Royal Sanitary Institute* will be issued quarterly instead of monthly.

A CORRESPONDENT has pointed out that the radiographic contrast medium for urography referred to in a paragraph entitled "X-Ray Photography of the Renal System" in NATURE of March 23, p. 459, is the same substance as the German preparation marketed before the War as 'Uroselectan B'. It is being manufactured in Great Britain and sold as 'Pyelectan' by the Glaxo Laboratories, Ltd., and as 'Uropac' by Pharmaceutical Specialities (May and Baker).

ERRATUM.—In NATURE of April 6, p. 529, col. 1, line 15, the reference to the paper by Prof. E. Schrödinger should read "*Preuss. Akad.*, 1930" instead of "*Preuss. Akad.*, 1936".

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.*

In the present circumstances, proofs of "letters" will not be submitted to correspondents outside Great Britain.

Notes on points in some of this week's letters appear on p. 630. Correspondents are invited to attach similar summaries to their communications.

The Atmospheric Layer from which the Yellow Line in Twilight originates

Through measurements at the Pic-du-Midi, Garrigue[1] found that the average intensity of the yellow line in the night sky 10° above the horizon is about 2·8 times that at the zenith, from which Cabannes, Dufay and Gauzit[2] found the altitude of the layer emitting the yellow line to be about 130 km.

Bernard observed at Tromsoe the time at which the intensity of the yellow line *in twilight* suddenly drops. Assuming the excitation to be restricted to a region exposed to ordinary sunlight, and that, therefore, the disappearance of the yellow line takes place when the shadow of the solid earth exceeds a certain height (H_B), Bernard concludes[3] that the emission of the yellow twilight line is restricted to a layer below 60 km.

Bernard regards this result as in conflict with that of Cabannes, Dufay and Gauzit, which he considers to be based on unreliable data ; but as he is dealing with a different light phenomenon, for which the distribution with altitude of the excitation agency will be different from that of the night sky luminescence, there is not necessarily any conflict between the results.

On the basis of extensive observational material from Oslo, I have been able to show that *the yellow line is also emitted in twilight from a layer situated at the lower part of the auroral region.* By means of a small spectrograph of great light power, we took a series of twilight spectrograms, partly in the zenith and partly in a nearly horizontal direction. If, with Bernard, we assume that the emission of the yellow line is determined by the shadow formed of visible sunlight by the solid earth, then the observations near the horizon would give a greater upper limit (59 km.) of the effective emission layer than the spectra from the zenith (45 km.).

Assuming, however, that the yellow line is excited by some easily absorbed, probably ultra-violet solar radiation, and that the atmosphere below a certain height (H_S) acts as a screen for the effective solar rays, then *this screening height may be found from the condition that the spectra from the zenith and from the near horizon must give the same upper limit* (H_u) *for the emission of the yellow line.*

The observations from Oslo give for the effective screening height $H_S = 55$ km. and for the upper limit of effective excitation $H_u = 115$ km.

It is of interest to notice that the screening height is just above the region of relatively large ozone concentration. The effective height is found to be about the same in the evening and in the morning, showing that there is no noticeable time-lag in the emission process.

These results indicate an extra-terrestrial origin of the sodium from which the yellow line is emitted. It is possible that, in addition to the hydrogen showers previously dealt with[4], showers of sodium coming from the sun may enter the atmosphere. Possibly the hydrogen showers, in connexion with sodium and atmospheric oxygen, may account for the luminous night clouds. Our results regarding the position of the effective sodium layer also enable us to make certain estimates regarding the effective solar radiation. If it is ultra-violet light, it should be found somewhere in the interval 1900–3100 A. The screening limit (H_S) is due to ozone absorption, the maximum of which lies at about $\lambda = 2500$, or near the wave-length ($\lambda = 2412$) corresponding to the ionization potential of the sodium atom.

Absorption of the Hydrogen Line 1215·7 A. by Air

In a recent letter[1], S. E. Williams reports measurement of the absorption in air and oxygen of the first line of the Lyman series of hydrogen, Ly_a, at 1215·7 A. This problem is of interest because of the suggestion by Martyn *et al.*[2] that Ly_a radiation from solar eruptive areas may be responsible for radio fade-outs. Williams's result was that a path length of 0·04 cm. of oxygen reduces the intensity of Ly_a by a factor of one half. This represents an absorption coefficient about fifty times as large as that found in a recent determination of mine[3].

Without details of his experimental method, it is difficult to suggest any explanation for this startling disagreement. Since water vapour, carbon dioxide, and most organic vapours have relatively much larger absorption coefficients at this wave-length, small traces of impurities would be sufficient to explain a result that was much too high.

It is more difficult to imagine a source of error which would give too *low* a value for the oxygen absorption. Williams suggests that the absorbing oxygen in my experiment may have been largely dissociated. Ladenburg and Van Voorhis[4] were bothered by dissociation when measuring oxygen absorption in the 1350 A. region. The oxygen in their cell disappeared rather rapidly, probably as a result of the adsorption of atomic oxygen on the cell walls. I was aware of this possible source of error. However, my source was a largely 'atomic' hydrogen discharge, with very low intensity in the spectral region responsible for oxygen dissociation. In addition, observation of the pressure in the absorpton cell during a prolonged run showed that it did not perceptibly decrease. It is therefore felt that no considerable error could have arisen from dissociation, and that the lower value for the absorption coefficient of oxygen, which is in agreement with previous estimates[5], is the more reliable.

It should be pointed out that a law of absorption $\log I_0/I = \mu x + C$ (where I_0/I is the ratio of incident to transmitted intensity, μ the absorption coefficient, x the equivalent path length at N.T.P., and C a constant found by Williams to have a negative value) can scarcely be called 'usual', as stated by Williams. It presumably predicts zero absorption for the range $0 < \mu x < |C|$, and I can find no record of the actual observance of such a phenomenon. Williams refers to Shalow and Steiner[6] as having described a case in which the *absorption coefficient* μ (attributed to O_2–O_2 molecules) varies with the *square* of the pressure p. Reference to their article indicates that they found that $\log I_0/I = ap^2$ (where a is a constant). The usual law of absorption, which can be written as $\log I_0/I = \frac{\mu l p}{76}$ (where μ is the coefficient of absorption, l the *actual* path length, and p the pressure in cm.), then shows that μ is directly proportional to p, not to p^2. They found no evidence of zero absorption over a finite pressure range.

Rotational Analysis of the Band Spectrum of Boron Monobromide

THE $^1\pi \rightarrow {}^1\Sigma$ spectrum of the molecule BBr[1] has been photographed in the second order of a 6·5 m. concave grating. The light source was an uncondensed discharge through BBr_3-vapour in a pyrex H-type tube fitted with quartz window and nickel electrodes. The rotational structure of the (0,0)-band at 2950 A. is partially resolved into lines. Measurements in the P-, Q- and R-branches, where lines up to $J \sim 90$ can be observed, make a complete analysis of this band possible. The constants of the BBr-molecule are found to be:

$$\begin{array}{llll|llll} {}^1\Sigma+ : & B''_0 = 0{\cdot}487 & \text{cm.}^{-1} & & {}^1\pi : & B'_0 = 0{\cdot}496 & \text{cm.}^{-1} \\ & D''_0 = -0{\cdot}90\times10^{-6} & ,, & & & D'_0 = -1{\cdot}25\times10^{-6} & ,, \\ & r''_0 = 1{\cdot}890 \text{ A.} & & & & r'_0 = 1{\cdot}875 \text{ A.} & \end{array}$$

Owing to the small difference of the constants B' and B'', the constants D' and D'' determine the form of the branches, which are rather unusual, the Q-branch forming two heads, one at the zero line, the other at $J \sim 100$. The value $B'' = 0{\cdot}487$ of the ground state together with the ground frequency $\omega e'' = 684{\cdot}0$ cm.$^{-1}$ gives for Mecke's bounding constant $k = \omega^2/4B$ the value 240,000 cm.$^{-1}$, confirming very strikingly the value calculated formerly from AlCl data for the group of halides of metals of the third group in the periodic system.

The full paper will appear shortly in *Helv. phys. Acta.*

A Photographic Method of Studying β-Ray Absorption by $^{32}_{15}$P

IN a previous communication[1], I pointed out the photographic action of artificial radio-elements; as an application of this, it has been possible to study the β-ray absorption of radiophosphorus through aluminium. Radiophosphorus was prepared by irradiating carbon disulphide by means of the neutrons emitted from 900 mgm. radium plus beryllium; its concentration was effected by means of an electric field[2]. The solutions containing $^{32}_{15}$P (20–200 × 10^3 kicks per minute) were evaporated to dryness on a water-bath in leaden vessels 1·5 cm. × 12 cm. × 0·3 cm. In order to establish the absorption curve, a series of aluminium absorption screens of increasing thickness (0·1–1·06 mm. and every 0·1 mm. up to 1 mm.) were placed between a Kodak X-ray film and each of these vessels. The photographs obtained were checked by means of a Zeiss microphotometer.

According to Bothe[3], who studied the blackening of a photographic plate as a function of the β-ray intensity, the photographic density D is proportional to the number of impinging electrons up to $D = 1$. The mass absorption coefficient can be deduced from the logarithmic absorption curve.

On the other hand, the results of measurements with a Geiger-Müller counter show, from 1·5 mm. aluminium onward, an incurvation of the logarithmic absorption curve toward the thickness axis. However, the curve is linear between 0 and 1 mm. aluminium, and it is possible to calculate the mass absorption coefficient μ/ρ.

Microphotometer deductions yield $\mu/\rho = 9{\cdot}27 \pm 0{\cdot}11$, whereas Geiger-Müller counter and electrometer methods give $\mu/\rho = 8{\cdot}55 \pm 0{\cdot}20$ and $\mu/\rho = 8{\cdot}51 \pm 0{\cdot}02$ respectively.

Thus the intensity of β-rays emitted from an artificial radioelement can be determined by a photographic method.

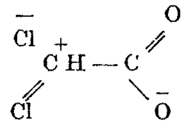
Resonance in the Chloroacetic Acids

IN addition to heat data, internuclear distances, and electric dipole moments, dissociation constants are now being used to determine whether or not possible valence bond structures contribute to the actual state of a molecule[1].

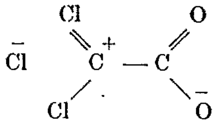
It is suggested that the dissociation constants of the three chloroacetic acids furnish such information. These acids present an interesting problem. The relevant data[2,3] are: CH_3COOH, $K = 1{\cdot}7 \times 10^{-5}$; $CH_2ClCOOH$, $K = 1{\cdot}4 \times 10^{-3}$; $CHCl_2CO\,OH$, $K = 5{\cdot}1 \times 10^{-2}$; CCl_3COOH, $K = 1{\cdot}2$. Now monochloroacetic acid has a dissociation constant about eighty times that of the unsubstituted acid, the reasonable explanation being that the strong dipole $\overset{+}{C} - \overset{-}{Cl}$ ($\mu_{Cl} = 1{\cdot}5\,D$) has been substituted for the weak dipole $\overset{+}{H} - \overset{-}{C}$ ($\mu_H = 0{\cdot}4\,D$). Di- and trisubstitution, however, lead to dissociation constants 3,000 and 100,000 times that of the parent acid.

Let μ_{Cl} be the moment of the C—Cl link in chloroacetic acid. The resultant moment (μ_R) of the two C—Cl links in dichloroacetic acid is $2\mu_{Cl} \cos \theta/2$, and for the three C—Cl links in trichloroacetic acid it is $\mu_{Cl}\,(6 \cos \theta + 3)^{1/2}$, θ being the tetrahedral angle, and neglecting dipole interaction. It is clear that no functional relationship can be traced between μ_R and K, since the μ_R's are all of the same order of magnitude, being in the ratios 1 : 1·2 : 1. It is also probable that dipole interaction reduces the resultant moments of the dichloro and trichloro groups, as shown by the dipole moments of methyl chloride, methylene chloride, and chloroform[4].

Some other factor must thus enter and succeed in strongly enhancing the dissociation constants of the di- and tri-substituted acids. It is suggested that this additional factor is resonance, which preferentially stabilizes the ionic forms. In the mono-substituted acid, the inductive effect of the C—Cl dipole is the enhancing influence, but in the case of the di-substituted compound, four conjugated structures of equal energy of the type



contribute to the actual state of the ion, the energy of resonance effecting stabilization. With trichloroacetic acid, twelve structures of the type



contribute, quantum mechanics leading also to the conclusion that each C—Cl bond length will be equal to and approach the double bond value[5]. Because of the separation of charge, these structures would not be expected to be as stable as the normal structures, but a linear relation does exist between log n and log K for the three chloro acids with $n = 2$, 6, and 14. It may be mentioned that electron diffraction investigations have established the facts[6] that the C—F bond distance in methyl fluoride is 1·42 A., whereas it is 1·36 A. in methylene fluoride, indicating the existence of structures of the type now postulated.

History of the Vacuum Flask

SIR WILLIAM BRAGG, in the brief account of his lectures on Dewar's research published in NATURE of March 16, mentions that vacuum vessels were made in the early days by C. E. Muller, who was a German glassblower settled in London. Though this is undoubtedly correct so far as it goes, I think that it may leave the wrong impression that Muller made the first vacuum vessels. Such an impression would be unjust to the memory of Dewar's assistant, R. N. Lennox, who actually made the first vessels. They were pointed out to me by my father a few weeks afterwards, on Lennox's bench as Lennox's work. My father's assistant, George Gordon, who had seen Lennox making them, showed me the method which he had seen Lennox use, making a small cylindrical vessel as a demonstration for me. To make spherical vessels was rather beyond Gordon's skill, and later he got Lennox to show me this. The early vessels used by Dewar for some time were of Lennox's make, and if I am not mistaken, some of them are still preserved at the Royal Institution. I should recognize them without doubt. It is likely that Muller was the first to make such vessels outside the Royal Institution, but I do not think that he had arrived in London when Lennox first made them. I was in the habit of frequenting his shop as soon as I learnt of its existence.

Aurora and Magnetic Storm of March 24-25

THE aurora and great magnetic storm of March 24–25 was followed by a second display and storm of only slightly less intensity on March 29–30. The first storm began 24d. 13h. 45m., and ended abruptly 25d. 13h., the later phase from 5h. being characterized by unusually large and rapid oscillations. This storm was greater than that of the great aurora of January 25, 1938, the range in declination being more than 150′, and in horizontal force more than 750 γ, being beyond the limits of registration in both elements. It was preceded by definite disturbances of moderate intensity from 20h. to 23h. on March 22, and from 20h. 30m. on March 23 to 1h. on March 24, and was followed by a notable disturbance from 20h. on March 25 to 3h. on March 26, the series forming a well-marked sequence at about one day's interval.

The second storm began on March 29 at 16h., and was dying down when the record was taken off the instruments at 10h. on March 30. The range in declination was 127′ and in horizontal force again more than 750 γ, being beyond the limits of registration, but apparently to a less extent than in the previous storm.

This second storm could easily be attributed to the influence of the large sunspot which crossed the central meridian on March 26·3, but it is difficult to assign this spot as the cause of the earlier storm, as in this case, allowing for time of transmission, any emanation from this area would have had to be emitted at a very great angle to the solar radius, which is not easily accounted for.

Relativity of Time

In Prof. H. Dingle's article on "The Relativity of Time"[1] and the correspondence that has followed, it is taken for granted that, while the Fitzgerald contraction can be detected experimentally, the slowing up of a moving clock cannot. Prof. J. W. Campbell[2], while disagreeing with Prof. Dingle on other points, is in agreement on this point. This, if it were true, would indicate a surprising lack of symmetry between time and space; but the following considerations show that there is in fact no such lack of symmetry.

The Lorentz transformation relates the space and time measures adopted by two observers in relative motion on the assumption that the observers use *independent* and *indistinguishable* experimental procedures and apparatus. If a stationary observer determines the time by measuring the rest-mass of sand flowing through an hour-glass at rest at the origin, then the moving observer must be assumed to determine the time as the *rest*-mass of sand flowing through an hour-glass, indistinguishable from that used by the stationary observer, and moving with the moving observer's origin.

The slowing down of a moving clock is deduced from the Lorentz transformation on the supposition that the readings of the moving clock could be used by an observer moving with it so as to satisfy the above requirements: in other words, the clock could be used by an observer moving with it without his knowing that it was moving. The predicted slowing down does not, therefore, apply to the moving clock suggested by Prof. Dingle in which the mass of sand flowing through an hour-glass is measured in the *stationary* co-ordinate system; for, if the observer moving with the clock does not know that it is moving, he cannot recognize the stationary co-ordinate system in which the mass is to be measured.

Now consider a uniformly moving clock A that satisfies these conditions, and let B be a stationary clock that is indistinguishable from A. Suppose that the positions of the clocks coincide when the reading of A is t_0. Let light signals be sent out from A when its readings are $t_0 - t_1$ and $t_0 + t_1$, and let these signals reach B when its (that is B's) readings are t_2 and t_3. The slowing up of the moving clock is demonstrated by the inequality $2t_1 < t_3 - t_2$. This experiment is closely analogous with that suggested by Prof. Dingle to detect the Fitzgerald contraction.

[1] Nature, 144, 888 (1939).

[2] Nature, 145, 426 (1940).

I think Dr. Powell's letter is based on a misunderstanding. I did not say that it was impossible to detect experimentally the slowing-down of a moving clock. My point was that whatever slowing-down was detected would not necessarily be in the Fitzgerald ratio unless the clock was an 'ideal' one, and that we could not check the relativity requirement with regard to time measurement by experimenting on actual clocks, because if they did not confirm it, the proper deduction would be simply that they were not ideal. The "lack of symmetry between time and space" thus implied is not at all "surprising". It exists because we can make an 'ideal' measuring rod but not an 'ideal' clock. You cannot, in fact, define the standard unit of length without implying the existence of the measuring instrument—the material bar. The unit of time, on the other hand, cannot be embodied in a material instrument. The best we have, the rotating earth, itself needs slight correction, and experiments on relatively moving earths are, to say the least, difficult. (Incidentally, I wonder if Dr. Powell and Prof. Campbell have considered the case of relatively moving sundials?)

Much confusion is introduced into the subject by multiplying observers. The special theory of relativity can be completely deduced by re-defining length as $l\sqrt{1-v^2/c^2}$ instead of l (where l is the length of a body measured by a relatively stationary rod and v is whatever velocity the body may have in the arbitrary co-ordinate system chosen), and following out the logical implications of the change in all other measurements. This can be done by a single observer, who can choose two co-ordinate systems and compare them. Suppose he has two measuring instruments (say clocks), A and B, one moving with velocity v relatively to the other. He can choose which he pleases to be at rest. If he chooses A, then B is running slow: if he chooses B, then A is running slow. That is how much "objective reality" there is in the slowing-down. If he makes an experiment to see which is "really" running slow, he must make some calculations from his observations to get his result, and the formulæ he must use will depend on his choice of co-ordinate system. They are such that he will always find the "moving" clock, whichever it is, to be running slow, when corrected to the "ideal".

This way of looking at the matter should dispose of the question, which every correspondent has raised, about the measurement of the "moving" mass of sand by the "stationary" observer. A single observer, given the definition of mass (a definition which is not satisfied by "rest-mass", for that is not conserved), has to measure the mass of a body according to that definition, whether it is moving or stationary with respect to himself. If he has to move with it every time, then the mass of a moving body has no meaning, for the whole point of the relativity theory is that there is no absolute, but there is relative, motion. Further, all observers, however they are moving relatively to each other, will obtain the same measurements of similar bodies at rest with respect to themselves. There is no significance in an observer of an object "knowing that it was moving"; what he should have known was that it was moving or not, according to his choice.

HERBERT DINGLE.

Production of Tumours in Mice by Deoxycholic Acid

J. W. COOK[1] pointed out that the sterols and bile acids contain in their molecules condensed carbon-ring systems to which are attached a side-chain in such a position that a new 6-membered ring can be formed so as to give the 1 : 2-benzanthracene ring system without molecular rearrangement or group migration. The bile acids of the higher vertebrates are all mono-, di-, or tri-hydroxy derivatives of cholanic acid, which compound can be obtained *in vitro* from sterols by degradation, and the principal bile acids bear the names of lithocholic acid (3-hydroxy-cholanic acid), deoxycholic acid (3 : 12-dihydroxy-cholanic acid) and cholic acid (3 : 7 : 12-trihydroxy-cholanic acid). J. W. Cook and G. A. D. Haslewood in 1934[2] showed that, in the formation of dehydronorcholene from deoxycholic acid by the procedure of Wieland, such a ring-closure to the 1 : 2-benzanthracene ring system had actually occurred. Dehydronorcholene gave on dehydrogenation the benzanthracene hydrocarbon methylcholanthrene, which was found to be strongly carcinogenic. Afterwards, Fieser and Newman[3] showed that methylcholanthrene could be obtained also from cholic acid, which is the chief acid of human bile, and the parent hydrocarbon cholanthrene was synthesized by J. W. Cook, G. A. D. Haslewood and A. M. Robinson[4] and shown to be carcinogenic.

The discovery that a carcinogenic compound could be obtained from deoxycholic acid led us to test for possible action of this kind the acid itself, which was applied in solution in a mixture of alcohol and benzene to the skin of 20 mice in the ordinary way. An epithelioma at the site of application developed in a single mouse in 776 days. The experiment was repeated upon, in all, 80 mice, of which some lived more than 800 days, but no more tumours were obtained. Afterwards, deoxycholic acid was injected in sesame oil into the right flank of 10 mice of mixed stock, of which 5 lived for more than 6 months. Of these five, three developed at the site of injection spindle-celled tumours of the type usually produced by carcinogenic compounds and were killed on the 351st, 355th, and 367th days. The tumours were regarded as malignant on histological grounds, but did not grow when transplanted into other mice of mixed stock. These mice had received 15 injections containing in all 70 mgm. of deoxycholic acid in 300 days. This is, of course, a large amount, and the time required for the development of tumours is long. However, the experiment was repeated using 10 mice of the strain C_3H which, of eight strains examined by Andervont[5], is placed first in the order of susceptibility to subcutaneous tumours induced by carcinogenic hydrocarbons, and of these mice one has now developed a spindle-celled tumour in 155 days (that is, a period less by 200 days than that required by the stock mice) after receiving a total of 28 mgm. in the course of six injections. These results confirm those of Vittorio Ghiron[6], announced at the Third International Cancer Congress at Atlantic City in September 1939, who says "Desoxycholic acid elicited transplantable subcutaneous fibro-sarcomas in a high proportion of the mice and rats injected. This is believed to be the first experimental production of malignant growths with a compound that exists under some conditions in the human body". We have not found any more detailed publication by Ghiron of his results.

Occasionally, tumours are produced in mice by sesame oil alone (W. U. Gardner, personal communication to Dr. Hieger) but we have obtained negative results with many compounds in this solvent, and we do not think that the incidence of tumours recorded above could be attributed to it. We have no evidence that deoxycholic acid can be converted *in vivo* into methylcholanthrene, but at the same time the slow action and large amount required of the acid, and the superiority of injection over external application, are compatible with conversion into some more active compound. Shear[7] obtained negative results by injection of deoxycholic acid, and cholic acid, *sub cutem* in mice, but a single injection only, in glycerol, was given. We are carrying out further experiments with deoxycholic and cholic acids.

Several other investigations in progress here are concerned with the liver in relation to carcinogenesis. Thus Dr. L. D. Parsons[8] has described the increased flow of bile in some tumour-bearing mice, and the use of bile in preparing cell-free filtrates from tumours; Dr. Hieger has confirmed the discovery of Schabad[9] that some extracts of human livers will produce sarcomas in mice, and is preparing these results for publication; and J. W. Cook[10] has described compounds (2 : 2′-azonaphthalene and its transformation product 2 : 2′-diamino-1 : 1′-dinaphthyl) which have a specific action in producing malignant tumours of the liver.

We are indebted to the British Empire Cancer Campaign for a grant which has supported this work.

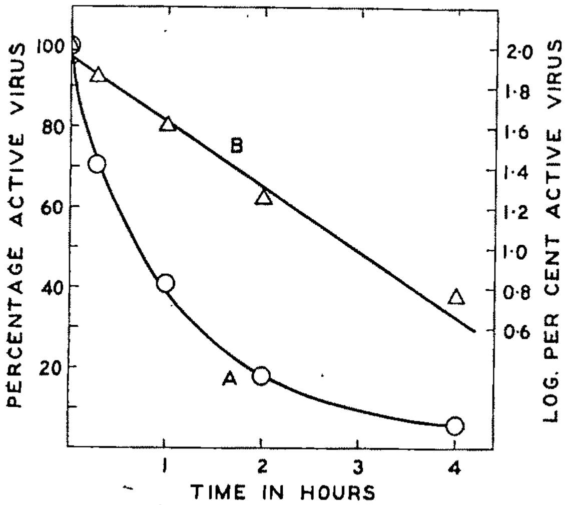
Some Effects of Salicylate on Plant Viruses

DURING an investigation into the effects of various anions on the precipitation of the paracrystalline solid phase of tobacco mosaic virus nucleoprotein (*Marmor tabaci*, var. *vulgare*, Holmes) from its solution in water, the salicylate ion was found to behave differently from other anions. For each salt there was found a critical concentration at and above which the virus was precipitated from solution in the form of spontaneously birefringent microtactoids or fibres. The white precipitate of virus nucleoprotein



GRAPH ILLUSTRATING THE RATE OF INACTIVATION OF PURE TOBACCO MOSAIC VIRUS BY POTASSIUM SALICYLATE (1·0 *M*.) AT *p*H 7 AND 30° C.

is still fully infective and may be redispersed to give a clear solution by mechanical agitation or dilution as described previously[1]. However, the precipitate produced by solutions of potassium salicylate at concentrations above 0·46*M*. is very different in character from that obtained with other salts. It consists of an insoluble, amorphous, white, granular solid deposit of denatured protein. Mechanical agitation or dilution does not cause re-solution. At the same time the virus loses its infectivity irreversibly. The accompanying graph illustrates the rate of inactivation of a 0·2 per cent solution of the pure virus by 1·0*M*. potassium salicylate at *p*H 7 and 30° C. The straight line nature of curve *B* indicates that the rate of inactivation is logarithmic. The rate of inactivation is greater the greater the concentration of salicylate and is markedly influenced by the temperature. With solutions of salicylate of the order of half molar there is only a partial inactivation, and a steady state appears to be set up after a few hours. At a concentration of 0·1*M*. there is no loss of infectivity, of stream double refraction or solubility after a contact of forty-eight hours. Denaturation, loss of stream double refraction and of infectivity all run parallel.

The virus of tomato spotted wilt (*Lethum Australiense*, var. *typicum*, Holmes) is very much more susceptible to the inactivating action of salicylates. Suspensions of it are rendered inactive in one hour (at *p*H 7 and 30°) by a 0·1*M*. solution of potassium salicylate. In this case cystein was used to arrest oxidative inactivation of both control and test suspensions.

Salicylates are known to cause denaturation of hæmoglobin[2,3], but the action appears to be reversible and of a different nature from that just described. It is likely that a study of the reaction of salicylates and related compounds on viruses will throw some light on the structure of virus proteins.

Coprophagy in the Rabbit: Origin of 'Night' Fæces

IN a previous communication[1] it was mentioned that there were significant differences in ash content between the ordinary 'day' fæces of the rabbit and the softer 'night' type obtained when coprophagy was prevented by collaring. Further investigation has shown even more striking differences in respect of other constituents, notably in protein and fibre.

A rabbit was fed for a week on a diet consisting of equal proportions of bran and oats at the rate of 50 gm. per day and the ordinary fæces collected. It was then provided with a large wooden collar and 'day' and 'night' fæces collected separately. Analysis showed that the 'day' fæces were very similar to the ordinary fæces of the uncollared period but very different from the 'night' fæces. Data on the food and on the two types of fæces, all referred to a dry matter basis, are as follows:

	Food (per cent)	'Day' fæces (per cent)	'Night' fæces (per cent)
Crude Protein ..	14·7	9·2	28·5
Ether Extract ..	5·2	1·7	1·1
Crude Fibre ..	11·7	28·9	15·5
N-free Extractives	63·6	52·0	43·7
Total Ash ..	4·8	8·2	11·2
P_2O_5	2·1	2·9	5·0
Na_2O	—	0·15	0·3
K_2O	—	0·65	2·1

Of the 28·5 per cent so-called 'crude protein' (total N × 6·25), 25·8 per cent was insoluble after treatment with copper hydroxide, as in the method for determining 'true protein', and about half was readily soluble when incubated with pepsin-HCl at 37° C., and the suggestion is that it is largely bacterial debris. This rise in protein nitrogen, in conjunction with reduction in fibre content as compared with 'day' fæces, suggested cæcal origin of 'night' fæces and a further experiment was carried out to test this point.

A rabbit was collared and fed as before on a bran–oats mixture, 50 gm. being supplied at 9 a.m. each morning. Of this about two thirds was consumed by 5 p.m., the remaining third being cleaned up before the following morning. 'Night' fæces were collected for four days and the rabbit was killed at 9 a.m. on the fifth morning. Considerable food residues were found in the stomach, but very little in the intestines or rectum. The cæcum contained a little fluid material the dry matter of which corresponded to only 4 gm., compared with more than 15 gm. for an uncollared rabbit killed later in the day. Analyses of cæcal contents and of 'night' fæces collected prior to killing were as follows:

	Cæcal Contents (% dry matter)	'Night' fæces (% dry matter)
Crude Protein	39·9	30·0
Total Ash	11·2	11·1
P_2O_5	4·4	4·2
Na_2O	1·9	0·5
K_2O	1·2	1·7

The close similarity in composition of the 'night' fæces with residual cæcal contents strongly suggests a long sojourn of the former in the deeper regions of the cæcum and subjection of material from the small intestine to prolonged bacterial action, resulting in increased percentage of protein associated with concomitant reduction of fibre and other non-nitrogenous dry matter. The composition of the 'day' fæces, particularly their higher fibre content and correspondingly lower 'crude protein' (including any undigested nitrogenous debris), suggests more direct passage through the gut with limited sojourn at the sacculus end of the cæcum.

The broad statement by Madsen[2] and by Taylor[2] that the two types of fæces are due to variations in "intestinal rhythm" provides no explanation of the actual sequence of events. The sequence now suggested is a partial filling of the deeper regions of the cæcum as the food contents pass on from the small intestine, associated with a partial more direct passage of digested material into the colon during the day, followed by extensive emptying of the deeper regions of the cæcum at night. The more regular passage of 'day' material presumably gives time for greater inspissation and a drier residue, the wetter 'night' fæces being accounted for by more rapid discharge of the deeper cæcal contents.

According to this view, the 'day' fæces would represent less completely digested food debris and this might be expected to be the portion more readily re-eaten. Although some 'day' fæces are reconsumed, the striking feature is the total disappearance of the more fully digested 'night' fæces when the inhibiting collar is removed. The 'night' fæces, however, are rich in protein and presumably swarming with bacteria capable of attacking cellulose. Is this of any advantage to the rabbit ?

Male Behaviour of the Female Starling (*Sturnus v. vulgaris*, L.) in Autumn

Witschi and Miller[1] have shown experimentally that the yellow bill colour of the starling in the breeding season is induced by male sex hormone. This yellow colour does not develop after the removal of the ovary or the testes, but in such castrated animals it may be induced in either sex by injections of androgenic substances. Œstrogenic substances have no effect on bill colour. It is concluded that the ovary produces male sex hormone, and that the most prominent secondary sexual character of the female starling is in fact a male character.

It has now been observed that the bills of adult British starlings of both sexes begin to turn yellow at the end of October, the time when the testes first show signs of activity. As the change in bill colour is a specific indication of the presence of androgenic substances, it is clear that in autumn both ovaries and testes are secreting male sex hormone. This has been found to have a marked effect on behaviour. At this time of year there is a burst of song which continues throughout November, and although in the breeding season the male alone sings, in autumn the habit is also developed by the female. This has been established partly by observation and partly by the examination of birds shot while singing. A similar effect has been produced experimentally by Leonard[2], who showed that the female canary, *Serinus c. canarius* (L.), when injected with male sex hormone, sings like the male. The song of the starling decreases in volume in December and January, particularly in severe weather, and when, in late February, it again increases it is produced by the male alone. At this time the ovary is growing and is probably secreting female sex hormone in such quantity that any effect on behaviour due to the presence of male sex hormone is obscured. The continued yellow coloration of the bill is proof, however, that male sex hormone is still being produced in the female bird.

The autumn change in bill colour, with its associated behaviour, occurs only in the British starling. The Continental birds present in the British Isles in autumn and winter retain the dark bill until January, and there is no autumn song by either sex. It has already been shown (Bullough and Carrick[3]; and unpublished) that the gonads of these immigrant starlings mature later in the season than those of the British birds.

The occurrence of male behaviour in autumn has been observed in the females of several other species of birds, and it is probable that these, like the female British starling, are under the influence of male sex hormone. In the robin, *Erithacus rubecula melophilus*, Hart., for example, Lack[4] has shown that in autumn individuals of each sex stake out territories and hold them with fighting and song. In this species, as in the starling, normal female behaviour reasserts itself early in the year when the female birds abandon their own territories and enter those of the males. This apparently widespread phenomenon of male behaviour on the part of female birds in autumn has proved difficult to explain in terms of ecological factors alone, and it is probable that other aspects of animal behaviour will be better understood when it becomes possible to correlate them with the condition of the endocrine balance.

Chalk Landscape

The communication of Lord Kennet of the Dene[1] reminds me of a note I wrote recently in an account of the ice storm of the end of January and of the thaw that occurred a week later. On the evening of February 3 rain began and by the morning of February 4 there was a strong thaw. But the ice below the snow and the frozen ground did not let the water soak away, with the result that there was much flooding. In the Cotswolds water poured over the frozen slopes, and at Bagendon the valley became a raging torrent four to five feet deep. Even here, 700 ft. above the sea, there was much flooding and for a time some roads were impassable. It has occurred to me more than once when watching the run off of water in a thaw after the ground has been frozen that such scenes must have occurred in the south of England on a much larger scale every spring during the Ice Age, and I have wondered whether this may not have contributed, or may not have been the chief cause, in the formation of the dry valleys of the chalk country.

Government Recruitment of Scientific Workers

The recent valuable leading articles to Nature have stressed the need for a scientific approach to many of our present national problems, Experienced men of science are necessary to ensure that scientific knowledge is properly applied and any developments which affect the recruitment of scientific workers should be critically considered.

It has come to the notice of the Association of Scientific Workers that certain Government departments have, since the beginning of the War, engaged scientific workers on a temporary basis at very low salaries. Both the temporary nature of the appointment and the low remuneration demand urgent attention. It is true that many civil service posts are now described as temporary appointments although they carry the same salary and pension rights as before the War; but the new feature of the appointments to which I refer is the absence of pension rights and the unreasonably low level of the salaries.

It appears that new low grades are being created without any reference to the scheme of the Carpenter Report, which formed the basis of the conditions of employment of men of science in Government departments, and which was accepted by the Department of Scientific and Industrial Research. In urging the necessity for an early revision of these temporary 'extraordinary' posts, I would recall the fact that after the War of 1914–18 certain men of science were kept in such temporary posts for periods up to ten years. The second aspect of the matter, namely, the poor remuneration, is perhaps even more important. In the cases referred to above the personnel was drawn from the Central Register, and possessed qualifications which would normally command a much higher salary than that offered. It appears that there may be two explanations of this state of affairs: either a number of highly qualified people have by mischance been appointed to junior posts, or else it may be a definite policy of the Treasury to recruit men of science to Government service at unusually low salaries. In either case, the matter should receive the attention of all professional scientific bodies.

Lastly, the difficulty of learning the conditions under which appointments are at present being made should be emphasized. The normal practice of advertising scientific posts has been largely replaced by direct approach through the Central Register. The greater facility with which suitable personnel can thus be found is an obvious advantage; but some means should be found whereby scientists in general can take cognizance of the new conditions of employment which are being imposed on them. Since so many of these new appointments are in Government service, it might suffice if there was a regular publication from time to time of the terms of employment. Such information should be pressed for by the Parliamentary and Science Committee.

Points from Foregoing Letters

From spectrograms of twilight, taken in the zenith and horizontally, L. Vegard concludes that the yellow line of twilight comes from the lower part of the auroral region, and is due to extra-terrestrial sodium, possibly emitted by the sun.

J. Govaerts finds it possible to study the β-ray absorption of $^{32}_{15}$P through aluminium by means of a photographic method. The results are in good accord with those obtained by other methods.

The inductive effect of the substituted dipoles does not completely account for the dissociation constants of mono-, di-, and trichloroacetic acids. An explanation is put forward by H. O. Jenkins in terms of resonating structures involving C—Cl bonds of partial double-bond character. A linear relation exists between log n, where n is the number of possible valence bond structures, and log K, where K is the dissociation constant.

Lord Rayleigh writes to point out that the first vacuum vessels were made for Sir James Dewar by his assistant R. N. Lennox, and that they were only made later by C. E. Muller.

It has been asserted that the slowing up of a moving clock cannot be detected experimentally. F. C. Powell describes an experiment that appears to contradict this assertion. In his reply, H. Dingle says that such experiments are possible, but that they cannot confirm or deny the relativity requirement. He still maintains that his 'mass-clock' is a valid instrument.

Deoxycholic acid, one of the acids present in the bile of the higher vertebrates, including man, has been shown by J. W. Cook, E. L. Kennaway and N. M. Kennaway to produce spindle-celled tumours when injected *sub cutem* in sesame oil into mice. Deoxycholic acid has been shown previously to be convertible *in vitro* into the cancer-producing compound methylcholanthrene.

R. J. Best has found that neutral solutions of potassium salicylate inactivate the viruses of tobacco mosaic and of tomato spotted wilt. In the presence of potassium salicylate at suitable concentrations, solutions of tobacco mosaic virus deposit a solid, insoluble, denatured, inactive virus protein, the solution at the same time losing its anisotropy of flow. The rate of inactivation is logarithmic.

A. Eden reports that there are pronounced differences in chemical composition between the 'day' and 'night' fæces of the rabbit, chiefly in crude protein, fibre and mineral content. The close similarity in composition between the dry matter of the 'night' fæces and the cæcal contents suggests that the former are derived from material which has been subjected to prolonged bacterial action in the cæcum.

It has been observed by W. S. Bullough and R. Carrick that in autumn the bills of female British starlings start to turn yellow, a fact which indicates that the ovary is secreting male sex hormone. Under the influence of this hormone the female bird sings like the male.

RESEARCH ITEMS

Removal of Front Teeth in Man

THE non-curative removal of two or more of the front teeth in man is a practice which has an almost world-wide distribution in space, while in time it has been observed in skulls dating from so far back as palæolithic times, occurring at this period both in Palestine and in Africa. Dr. Aleš Hrdlička, in a study of the practice (*Smithsonian Inst. Miscell. Coll.*, 99, 3 ; 1940), points out that the teeth, usually the incisors, but sometimes the canines, were not removed on account of dental caries or other pathological condition. By Neolithic times the custom was widespread over Africa, Australia, continental Asia and Japan, and had reached some parts of Europe. It still survives in parts of Africa, Australia, possibly Mongolia, and parts of South America. In America the custom had not been observed among either Eskimo or Indians, as it had died out entirely, while in the skeletal evidence, which was scanty, the loss of teeth was likely to be overlooked. The first record of it comes from the material obtained by Dr. Hrdlička himself in the Aleutian Islands and Kodiak Island. He has now listed a large number of instances from American and Siberian collections, his conclusion being that "there is ample evidence that non-curative removal of some to all of the front teeth has been a widespread procedure since Neolithic times in northern Asia and since the oldest known times in America. . . . It shows features indicating strongly that it was essentially a ritual sacrificial observance".

Fossil Man of Monte Circeo, Italy

AN account of the palæolithic caves of Monte Circeo on the borders of the Pontine Marshes, Italy, and of the fossil remains of Neanderthal man discovered there by A. C. Blanc in February, 1939, is contributed by him to the *Revue Scientifique*, 78, 1 (1940) ; it contains further particulars of the remains and of the circumstances of the find. These caves, of which there is a large number, are situated in a calcareous limestone ridge at the edge of the plain. Some have been known as the source of a fossil fauna and worked flints for a considerable period ; but although visited in 1817, no systematic examination of them was made until 1883. Between 1936 and the discovery of Neanderthal man in the Guattari Cave in 1939, M. Blanc had investigated thirty-one caves, in twenty of which the removal of the contents by wave action and other agencies had left traces of the pleistocene filling, making it possible in many instances to reconstruct the stratification even before excavation began ; while in ten were the remains of a fossil fauna and flora as well as of palæolithic industries. Up to the time of the discovery investigation had revealed that a cold fauna associated with Aurignacian was superimposed upon a warm fauna (*R. Mercki* and *E. caballus*) and a Mousterian industry. The present find of a Neanderthal skull was made in the third of a series of three communicating chambers in the cave, in which the floor of the first was covered with a heterogeneous collection of bones of a fossil fauna. The skull lay on the surface, completely free and surrounded by a ring of stones disposed in an oval. Bones of Bovidæ and Cervidæ were scattered about the chamber. Deposits on the walls pointed to a prolonged period of inundation. Staining indicates that the skull itself had also been half-submerged at the same time. The disposition of the skull and the evidently intentional enlargement of the foramen, which has been completely destroyed, point to funerary and magical rites, possibly a ritual feast. This would account for the absence of skeletal bones. In date, Monte Circeo man stands later than the Sacchopastore skull ; and probably when rockfalls closed the cave to occupation Würm II had already begun.

Causation of Silicosis

ALL dusts produced in industrial processes in excessive amount are injurious to the air-passages and lungs, but certain mineral dusts are the most harmful. These are liable to cause the condition known as 'silicosis', in which fibrosis and other changes occur in the lungs, frequently terminating in secondary tuberculous infection. Industrial experience pointed to those dusts containing a large proportion of free silica, such as quartz and flint, as being the most dangerous, and the material must be in the form of fine particles less than 10 μ in size, but not ultra-microscopic. In a recent publication, F. W. Simson and A. S. Strachan have tested the silicosis-producing action of a number of mineral specimens (*Pub. South Afr. Inst. Med-Res.*, 9, 95–122 ; 1940). These included sillimanite, orthoclase, muscovite, rutile, quartz and several mine dusts, glass and a residue from human silicotic lung ; all were reduced to particles of an appropriate size distribution. Several doses of suspensions of these dusts were injected intravenously into rabbits. The animals mostly survived at least a year before examination, when the tissues chiefly affected were found to be those of the liver, spleen, lymph-nodes and bone-marrow. Cellular nodules were formed with giant cells, the process culminating in dense fibrosis. The lungs were unaffected, as dust particles introduced intravenously do not reach the alveoli. Only the quartz, the mine dusts and the lung residue were active in causing the lesions, the inactive dusts—sillimanite, orthoclase, rutile, muscovite and powdered glass—producing no inflammatory reaction and no fibrosis. The experiments seem to conform with the current belief that quartz, flint, and other forms of *free* silica are the noxious elements in active dusts. The paper is illustrated with a number of plates of photographs of the affected organs and photomicrographs of the lesions present.

Glycolysis in Embryos

BY thorough freezing and grinding of the tissue, Meyerhof and Perdigon (*C.R. Soc. Biol.*, 132, 186 ; 1939) have prepared extracts of rat and chick embryo which produce lactic acid from glucose. The glycolytic power of the extracts after addition of cozymase is of the same order as that of the original tissues. The extracts also produce phosphoglyceric acid and lactic acid from hexose diphosphoric acid and pyruvic acid. These experiments support the idea that the reactions of glycolysis in all tissues involve phosphorylation and that the intermediate stages are similar to the processes occurring in alcoholic fermentation which were first revealed by Harden and Young.

Mosquitoes and Filariasis

IN 1924 Yamada reported that the mosquito common in Shanghai, *Anopheles hyrcanus* var. *sinensis*, was capable of acting as an intermediate host of *Wuchereria bancrofti*, although certain Culicines were more important as carriers. A series of tests have been carried out by Stephen M. K. Hu to determine the susceptibility of the Anopheles mentioned to experimental infections with the parasite (*Peking Nat. Hist. Bull.*, 14, 83 ; 1939–40). Specimens of Anopheles to the number of 381 were fed on a heavily infected case of *Wuchereria bancrofti*. They were allowed to live sufficiently long to permit the filarial larvæ to complete their development to the infective stage, and when dissected 80, or 20·9 per cent, were found with infective larvæ, to the number of 3·6 on an average to each mosquito. When Anopheles along with *Culex pipiens* var. *pallens* and *Culex vagans* were allowed to feed on an infected case, subsequent examination showed that the latter species had a higher percentage of positive infection as well as a larger number of infective larvæ to each individual. Natural infection shows the same result. Of 87 Anopheles and 245 *Culex pipiens* var. *pallens* collected at the same time in a filarial house in Woosung, 4·6 per cent of the former and 17·2 per cent of the latter were found with filarial larvæ.

Young Caranx in the Western North Atlantic

J. T. NICHOLS (*Bull. Bingham Oceanograph. Coll.*, Peabody Museum of Natural History, Yale University, 7, Art. 2 ; 1939) gives a key to the young Caranx of the West Indian Region. The distribution of these young fishes is interesting, both *Caranx ruber* and *C. crysos* occurring in the Gulf Stream, *C. bartholomæi* inhabiting the drifting Sargassum weed, usually at or beyond the edge of the current and not actually in the Stream itself. The Gulf Stream appears to be the nursery ground for *C. ruber* and *C. crysos*, the latter occurring far to the north-east, and it is shown that the young are of such a small size that they must drift far to the east before reaching a stage in which they can swim independently of the current. These two species with their young most confined to the Stream, grow into the slenderest and swiftest of the Caranx in this region, and, presumably, they have the widest range. A good series of the young of *C. crysos*, less than 50 mm. in length, shows that the character of pigment spots, some of which are large and conspicuous, are useful in distinguishing this species from its relatives at so small a size.

Purification of Insect-transmitted Viruses

SPECIFIC nucleo-proteins have been isolated from plants infected with the more stable viruses, but those pathogens which are only transmitted biologically, by grafting or insects, have not been so purified. F. C. Bawden and N. W. Pirie show, however, that this is possible (*Brit. J. Exp. Path.*, 20, 322–329 ; 1939). They used potato virus '*Y*' and Hyoscyamus virus 3, and succeeded in obtaining yields of liquid crystalline nucleo-protein between 0·5 mgm. and 3 mgm. per litre of infective sap. Such preparations were infectious, but the methods used in purification seemed to lower the infectivity without destroying the serological activity. The physicochemical properties of the preparations closely resembled those of potato virus *X*.

Intranuclear Inclusions in Virus-infected Plants

INCLUSIONS which occur in the tissues of host plants infected with virus diseases have all been described as intracellular. Animal viruses, however, induce, in addition, intranuclear bodies in the cells of their hosts. Basilios Kassanis has now described (*Ann. Appl. Biol.*, 26, No. 4, 705–709 ; 1939) two kinds of body in the cells of solanaceous plants infected with severe etch virus. One type of inclusion occurs in the cytoplasm and is similar to the common X-bodies ; the other occurs only in the nuclei. This type appears to be crystalline in the form of thin rectangular plates, and to resemble the inclusions associated with the polyhedral disease of silkworms.

Rooting of the Olive Tree

J. VIEIRA NATIVIDADE has published (*Agronomia Lusitana*, 2, 25–73 ; 1940) a very interesting note upon a method of root production in the olive which seems so far to have escaped attention. Excrescences on the base of the trunk have been known for centuries and used for purposes of propagation ; they contain much parenchyma with stored food reserves and possess dormant buds. Natividade's anatomical study now shows these excrescences also contain a number of root initials ; these arise near the vascular cambium and, as they enlarge, the root cap may often be cut off by the phellogen and buried in the cork. These excrescences may be formed at various levels in the trunk but are invariably linked with the ground by a cord-like strand on the trunk surface. These cords seem to represent aerial roots fused with the trunk and when they reach the ground they give rise to a root system. The accumulation of these excrescences and their linked basipetal cords form the typical fluted bole of the olive, and the whole original root system of the tree is replaced by the later root system developed from these superficial cords. This is true whether the original root system was that of a seedling, a cutting or a root stock. Thus the textbook instruction to propagate the olive by grafting in order to obtain a deep root system rests on a fallacious argument.

Carbohydrate Manuring

INDIAN soils normally contain much less nitrogen and organic matter than those of more temperate regions, and the use of molasses as a fertilizer has received considerable attention and met with some success. Recently, N. R. Dhar of Allahabad has claimed remarkable increases in nitrogen fixation by the use of molasses and other energy-rich materials, including fats. An account of this work was presented at the First International Fertilizer Congress in Rome in 1938 and is summarized by H. E. Z. Raczkowski in *Hadar* (Nov. 1938), the Palestine citrus journal. According to Prof. Dhar, carbohydrates, glycerol, paper, straw, sawdust, etc., increased nitrogen fixation. Light is said to be utilized as in photosynthesis. In field trials, 3 tons of molasses added 112 lb. of nitrogen per acre, and 10 tons fixed 270 lb. of nitrogen. The nitrogen thus fixed was retained in the soil much longer than when ammonium sulphate was added. In sterilized soil nitrogen fixation occurred in the complete absence of micro-organisms, provided light was available. It is thus claimed to be a photo-chemical process. Contrary to the general belief, Prof. Dhar says that fats are readily oxidized in tropical soils and provide considerable energy for nitrogen fixation.

Zea-Euchlæna Hybrids

D. S. LANGHAM (*Genetics*, 25, 82–108 ; 1940) shows that three out of the five characteristic differences between maize and teosinte are inherited as unifactorial characters. These are weak response : strong response to length of day, paired female spikelets : single spikelet and many ranked : single-ranked ear. The dominant character is given first in each case. The results support the theory that maize arose from teosinte by a few large-scale mutations and disagree with the view that maize and teosinte differ in thousands of genes.

Recent Trends in Earthquake Insurance

A. C. CHICK considered this subject in a paper presented to the annual meeting of the Eastern Section of the Seismological Society of America on June 9, 1939 (*Earthquake Notes*, 11, No. 3 ; Jan. 1940). Attention was directed to the strong motion seismograph developed by the Coast and Geodetic Survey, and the model experiments of Prof. Ruge to determine earthquake effects on structural designs. In particular, the volume of earthquake insurance became greater in the United States after the Long Beach earthquake, but decreased after the emotional effects of the earthquake had worn off. Soon after the Santa Barbara earthquake in 1925, the premium on earthquake insurance in California amounted to approximately three million dollars, but by 1928 this had dropped to approximately two million dollars, and by 1932 it had further fallen to three-quarters of a million dollars. In June 1939 the total premium on earthquake insurance written in the United States, as reported to insurance commissioners, amounted to about one million dollars. The large earthquakes in various parts of the world have had little influence on this, but quite a little activity in the United States was stimulated by the New England hurricane of September 1938. Chick concluded that the rates for earthquake insurance were still high compared with fire insurance rates, but that this must necessarily be so as long as the requests for this type of coverage came chiefly from those areas which were recognized as being seismically active.

Atomic Weight of Holmium

THE investigation of holmium with the mass-spectrograph has shown that the element is composed of one type of atom only, with a mass of 165. It is difficult to determine the chemical atomic weight with accuracy from this figure, as the packing fractions of the rare earth elements have not been directly determined, but can only be estimated from Dempster's packing fraction curve. If, however, the value $-0{\cdot}8$ is taken for this, and Smythe's correction factor (0·999725) is used, the value obtained for the chemical atomic weight is 164·94. O. Hönigschmid (*Naturwiss.*, 27, 855 ; 1939) points out that this is considerably higher than the international value of 163·5 at present accepted, the latter being probably too low in consequence of the presence of impurities, chiefly yttrium, in the holmium preparations used for analysis. A holmium preparation of a high degree of purity has now been obtained. X-ray methods show that it contained only $0{\cdot}013 \pm 0{\cdot}004$ at. per cent of yttrium, about 0·04 at. per cent of erbium, and 0·03 at. per cent of dysprosium, and less than 0·02 at. per cent of other elements. Analysis of the holmium trichloride obtained from this preparation gave as a mean the value 164·935 for the atomic weight. When corrected for the amount of yttrium present, the value becomes 164·944, which is almost identical with the value calculated from mass-spectrograph data.

Proton-attracting Properties of Liquids

RECENTLY many investigations in infra-red spectroscopy have been concerned with the properties arising from the formation of 'hydrogen bonds'. If a common solute, which can act as a proton donor, is dissolved in various proton-acceptor solvents (bases), the tendency to form hydrogen bonds should be governed by the strength of the base. To test this, Gordy and Stanford (*J. Chem. Phys.*, 7, 93 ; 1939 and 8, 170 ; 1940) have examined the OD band of CH_3OD in some fifty solvents. In benzene CH_3OD is monomeric and the OD band is at 2681 $cm.^{-1}$. The extent to which this band is shifted to longer wave-lengths on solution is taken as a measure of the strength of the 'hydrogen bond', and hence the stronger the bond the more basic the solvent. The power of solvents to form hydrogen bonds is in the order : esters $<$ aldehydes and ketones $<$ ethers $<$ amines. The effects of substitution and unsaturation on the proton-attracting power of the oxygen or nitrogen atom with which the OD forms a bond are discussed. Comparison of the observed shifts in location of OD bands with the dipole moments of the solvents shows no correlation between the magnitude of the moment and the extent of the shift. Thus the complexes are not formed entirely as a result of dipolar attraction. When the basicity constants are plotted against the wave-length shift a linear relationship is established from which, by extrapolation, the basicity constants of several solvents have been evaluated. A linear relationship exists also between the OD wave-length shift and the rate of semi-carbazone formation of some aldehydes and ketones. There is, too, close concordance between the shift and the solubility of monofluorodichloromethane (a proton donor) in various solvents.

Nuclear Reactions with Bismuth

THE Cambridge cyclotron has been used by D. G. Hurst, R. Latham and W. B. Lewis (*Proc. Roy. Soc.*, A, 174, 126) to investigate the reactions of bismuth bombarded with deuterons. The reaction $^{209}Bi(d, p)^{210}RaE$ was previously known from the work of Livingood, and the production of polonium by the reaction $^{207}Bi(d, n)^{210}RaF$ was found for the first time. The RaE decays to polonium with a half period about 5 days, so that the measurement of the polonium activity over a period of days provides a method for investigating the relative probability of the two nuclear reactions. A stack of aluminium foils thinly coated with bismuth was bombarded with deuterons, and the processes thus investigated for a range of deuteron energies. It is to be expected that the (d, n) reaction will occur if the deuteron enters the nucleus, while the $(d ; p)$ reaction is due to the Oppenheimer-Phillips process, in which the deuteron splits up on the surface of the nucleus and the neutron alone enters the latter. This view is, on the whole, borne out by the results of the measurements. The $(d ; p)$ reaction is apparently more probable than the other for all the energies studied, that is, up to 8 m.e.v.

DISTRIBUTION OF BRITAIN'S INDUSTRIAL POPULATION*

ALTHOUGH the Royal Commission on the Distribution of the Industrial Population, under the chairmanship of Sir Montague Barlow, completed its report in August 1938, the report was not signed and printed, owing to the international situation, until December 1939. The appointment of the Commission arose out of recommendations in a report of the Commissioner for the Special Areas, afterwards debated in the House of Commons, and its terms of reference covered the causes of the present distribution of the industrial population and the probable direction of any change in that distribution in the future; the social, economic or strategical disadvantages of concentration; and the remedial measures, if any, to be taken in the national interest. The minutes of evidence taken before the Commission have already been published independently, but the report includes among the appendixes a memorandum on the location of industry by Prof. J. H. Jones, analysing factors in location as well as post-War trends; some notes on garden cities, satellite towns and trading estates; and a memorandum on planning in some other countries by Mr. G. L. Pepler.

Consideration of the causes of the present distribution leads the Commission to conclude that in the absence of decisive natural factors such as the existence of coal or of an adequate supply of suitable water, industries tend to be located within easy reach of the market. The industries that have shown a relative expansion since 1918 are either local industries or industries in the location of which natural factors have not been decisive. The cost of power and transport is relatively low; in the past, such industries tended to settle in places like London and Birmingham, which were not suitable for the development of those 'basic' industries that are now declining; such places, therefore, became the legatees of the remainder of the industrial estate, particularly as they constituted or were near large markets. Moreover, the existence of cognate industries or common subsidiary industries, of industrial atmosphere and of a large and growing market, have accelerated a growth that was already taking place long before 1914.

In present conditions, it is difficult to predict the probable future course of trade or industry in Great Britain or elsewhere. Once normal and reasonable stable international conditions are established, however, it may be expected that the importance of the old 'basic' industries in the national economy may decline and that of other industries increase. Industrial areas containing the former will only be able to keep up with the national rate of general industrial progress if they stimulate within themselves a growth of the miscellaneous light industries in excess of the rate of growth of such industries in the country as a whole. While the attraction of London and the Home Counties may lose some of its force owing to the greater vulnerability of the area to attack from the air, the Commission sees no reason to suppose that, apart from this factor, and in the absence of some restrictive regulation by the Government, the trend to the south-east of England will be permanently checked when the rearmament policy has accomplished its purpose.

The Commission considers that the concentration of industry or of the industrial population in a large town or particular area should not, of itself, give rise to higher mortality rates than elsewhere or to other social disadvantages, provided that the town or area is well planned. The bad planning of the existing large towns and areas of industrial concentration in Great Britain, however, inflicts certain disadvantages on their inhabitants through bad housing, lack of space for recreation, difficulties of transport, congestion, smoke and noise, which are often accentuated by unsatisfactory economic conditions. These disadvantages are the result of the haphazard manner in which urban development has proceeded in the past, and could be remedied or greatly reduced by good planning. Accordingly, policy should be directed to the continued and further redevelopment of congested urban areas, where necessary, having due regard to the retention of the advantages of a well-planned town and the addition, so far as possible, of the cultural and physical aspects of the country; decentralization and dispersal of both industries and industrial population from such areas, and provision of checks to the further growth of London.

The economic advantages of concentration of industry in proximity to market, reduction of transport costs and availability of a supply of suitable labour are accompanied by disadvantages such as heavy charges on account of high site values, loss of time through street traffic congestion in the very large towns and the adverse effects on efficiency and output of the fatigue incurred by workpeople through long daily journeys between home and workplace, often under considerable discomfort. Strategical considerations further support a policy of decentralization or dispersal of industry from overcrowded areas, which is already desirable to counteract the social and economic disadvantages of concentration.

The report then reviews in turn related questions of town planning, garden cities, satellite towns and trading estates. The well-considered development of garden cities, satellite towns and trading estates should offer a useful contribution to the relief of overcrowded and congested urban areas, but such development is unlikely to be successful if left entirely to private enterprise on account of the magnitude of the financial commitments involved. Accordingly, the Commission recommends that the proposed National Industrial Board should examine and formulate the policy to be adopted in relation to the development or encouragement of such methods where decentralization or dispersal is desirable, including adequate provision for the requirements of industry, social and amenity requirements, avoidance of unnecessary competition, and due regard to strategical considerations.

Further chapters deal with population trends, the problem of the special and depressed areas in relation to the balance of industry throughout the country, different types of cities and the problem of congestion and some aspects of the problem of London. In regard to the special areas, the Commission recommends that the National Industrial Board should, in the light of the experience of the Special Areas legislation, study the location of industry throughout Great Britain with the dual object of anticipating cases where depression may occur in the future and encouraging before a depression crisis arises the development of other industries or public undertakings, and of encouraging a reasonable balance of industrial development throughout the various divisions or regions of Great Britain. Adoption of a regional system, it is considered, would materially facilitate several of the problems before the Commission.

---

* Royal Commission on the Distribution of the Industrial Population. Report. (Cmd. 6153.) Pp. x+320. (London: H.M. Stationery Office, 1940.) 5s. net.

From the evidence submitted, the Commission has reached the unanimous conclusion that the disadvantages in many, if not in most, of the great industrial concentrations constitute serious handicaps and in some respects dangers to the nation's life and development, and that definite action should be taken by the Government towards remedying them. The problems of the location of industry are national in character, touching on and overlapping those of agriculture, land, water, transport, roads, amenities, etc., and the solution must be sought along the lines of national inquiry and guidance. For the national action necessary in view of the nature and urgency of the problems, the Commission is of the unanimous opinion that a central national authority is required, the activities of which should be distinct from and extend beyond those within the powers of any existing Government department. The objectives of national action should be : continued and further development of congested urban areas where necessary ; decentralization or dispersal both of industries and population from such areas ; and encouragement of a reasonable balance of industrial development with appropriate diversification of industry throughout the country. The Commission is also agreed that the continued drift of the industrial population to London and the Home Counties constitutes a social, economic and strategical problem demanding immediate attention, and that the central authority, whether advisory or executive, should examine forthwith and formulate the policy or plan to be adopted in furtherance of the objectives indicated. The central authority should have the right to inspect all existing and future planning schemes and to consider the modification or correlation of such plans, where necessary, in the national interest. Appointment of a body of experts to examine the questions of compensation, betterment and development is also recommended, and the powers of the authority should include the collection and co-ordination of information relating to location of industry ; research ; collection of information as to the various natural resources which may be affected by industrial location ; advisory functions on problems of location ; and publicity and annual reports.

Differences of opinion are revealed in regard to the machinery of Government action. The majority report recommends that a National Industrial Board should be appointed by the President of the Board of Trade after consultation with the Ministers of Health, Labour and Transport and the Secretary of State for Scotland, for making research into, advising upon and regulating the location of industry. In addition to the functions already outlined, the Board should have power to establish regional bodies to study problems of industrial location, and it should be required to report what executive powers it requires generally for giving effect to the agreed objectives of national action. The Board should also from the outset be invested with power to regulate the establishment of additional industrial undertakings in London and the Home Counties, including power to refuse consent to the establishment of a new industrial undertaking unless it is established to the Board's satisfaction that the undertaking cannot be conducted on an economic basis elsewhere. Provision should be made, moreover, for the application by Order in Council of similar regulation to other specified areas.

These recommendations are signed with reservations by three signatories, Prof. J. H. Jones, Mr. G. W. Thomson and Sir William E. Whyte, who consider it should be the duty of the proposed new Board to give continuous study to the problem of achieving a well-balanced industrial society, and that the problem of location cannot be separated from the national problem of persistent unemployment. Accordingly, they recommend that the establishment of divisional or regional bodies should not be optional but a definite requirement of the scheme of regulation or control. They also insist that the Board should be required to report on the further powers required at the earliest possible moment ; that the powers of negative control apply equally to the whole country ; that the powers of the Commissioners for the Special Areas, so far as they bear upon the work and functions of the Board, should be transferred to the latter ; and that the Board should be in a position to offer the inducements they consider necessary to secure a better balance and greater diversification of industry throughout the country.

The minority report, which is signed by Prof. Patrick Abercrombie, Mr. M. H. Elvin and Mrs. Hichens, differs from the majority report in the stress it lays on the urgency of the problem and upon the necessity for granting far-reaching executive powers to a new Government department or one evolved from an existing department. The signatories consider that the unprecedented amount of new factory location taking place and the altered character of war risks with re-location involved make the problem an immediate one. The new ministry should take over some of the planning functions of the Ministry of Transport and possibly of the housing functions of the Ministry of Health, and the powers and functions of the Commissioners for the Special Areas should be transferred to it, with general application. Its functions would be inquiry and research to lead up to a systematized plan for distribution of industry on a national scale, with a better balance in the distribution of population, and, pending the evolution of such a national plan, control of changes in the present distribution of industry. The ministry would be assisted by a strong central advisory commission as well as by regional boards. The minister would be empowered to exercise negative control over the establishment and location of new industrial undertakings or extensions of existing ones, and to schedule areas in which development would be permitted or prohibited. He would be empowered to impose the requirements of the general development plan, prepared by the commission of research, upon regional and local planning schemes, as well as to authorize financial assistance to encourage desirable industrial location and proper planning, including the assistance of projects of national importance such as national parks. A dissentient memorandum in criticism of present planning powers and practice is contributed by Prof. Abercrombie.

PHYLOGENY AND TAXONOMY

A JOINT meeting of the Linnean Society and the Association for the Study of Systematics in relation to General Biology was held in the rooms of the Linnean Society on April 11, at which a discussion took place on phylogeny and taxonomy.

Mr. J. S. L. Gilmour, opening the discussion, distinguished between 'general' classifications, based on a maximum correlation of attributes, and 'special' classifications, based on selected attributes. Taxonomy has a clear aim of its own, apart from phylogeny, namely, the construction of a 'general' classification of living things for the purpose of conveniently summarizing empirically discovered correlations and of making predictions based on them.

The concept or 'relationship' was defined in terms of genealogical lineages and was regarded as only one of the factors making up phylogeny or the "history of the origin and development of groups". Relationship, thus defined, cannot be regarded as the *basis* of taxonomy, but rather as the *explanation* of the possibility of making a 'general' classification of living things with a high degree of correlation. A lineage classification, based on relationship, is really a special classification made for the purpose of correlating relationship with other attributes. The view that taxonomy is necessarily phylogenetic is an error due to a misunderstanding of the nature and aim of a 'general' classification.

Dr. O. W. Richards pointed out that, if evolution is a fact, a phylogenetic classification must exist. In addition, however, a classification can be made in which a large number and varied assortment of characters are correlated. Is such a classification the same as a phylogenetic one ? Pre-Darwinian and present-day taxonomic methods are, broadly speaking, very similar, but nevertheless evolutionary theory has had a profound effect on post-Darwinian taxonomy in two main ways : (1) series of groups showing progressive change are held to have some relation to evolutionary change, and this affects the taxonomic treatment of the groups ; (2) our general knowledge of the cause of evolution enables us to orientate such series. Whether these changes have always brought our classifications nearer the true phylogenetic one is often difficult to decide and must await crucial palæontological evidence. In the long run, a classification approximating as nearly as possible to phylogeny will prove practically the most successful.

Dr. T. A. Sprague agreed with Mr. Gilmour that a natural classification in biology is based on degrees of resemblance and difference, but not necessarily on maximum agreement in total characters. He pointed out that, apart from the difficulty of deciding what are unit characters, general plan of structure far outweighs details, and that greater weight should be assigned to non-adaptive than to adaptive characters. The natural classification in botany has been developed synthetically by a process of trial and error, and the characters eventually employed in the resulting groups have been observed, not arbitrarily selected. The fact that so many groups of the Angiospermæ, large and small, originally based only on external morphology, have been confirmed by independent consideration of their anatomical, cytological and biochemical characters, suggests that a high proportion of the recognized groups, from species to families inclusive, is monophyletic. In the absence of relevant fossil evidence, however, the general inter-relationships of the orders cannot be determined. Most phylogenetic trees of the Angiospermæ are based on hypothetical evolutionary floral progressions, and are essentially morphogenetic diagrams, representing postulated stages in general floral evolution. Agreement in general plan and non-adaptive characters between particular orders makes phylogenetic relationship between them seem highly probable, but the greater part of such phylogenetic trees seems to be purely speculative.

Dr. E. I. White stated that, primarily, taxonomy and the study of phylogeny are distinct and not necessarily interrelated. The former deals with the arrangement of organisms into groups determined by the number and nature of common characters, which might be arbitrary, while the latter is concerned only with the ancestry of organisms, that is, their true relationships, determined by the appraisement of characters common to the several organisms the selection of which cannot be arbitrary. Were all facts known, a phylogenetic tree and a sound taxonomic arrangement would coincide, but this postulates evidence in both space and time. It is the work of palæontologists to provide such evidence, and to them a taxonomic arrangement without a phylogenetic basis is only a temporary expedient due to lack of evidence.

Dr. Hamshaw Thomas, in a written communication, puts forward the view that, if phylogeny is to be built on a firm foundation, we must replace the present deductive methods by inductive reasoning based on the statistical investigation of empirically discovered correlations. We are at the parting of the ways ; the rejection of the classical concepts of floral morphology has reduced current phylogeny to a mass of ruins, and a century may elapse before it can be rebuilt. Meanwhile, supposed phyletic series based on typological morphology have no place in taxonomy, which should follow the principles of a natural classification laid down by Lindley more than a hundred years ago. If eventually such a classification suggests a course of evolution agreeing with that discovered by phylogenetic studies, so much the better, but at present taxonomy and phylogeny should develop independently.

Space will allow of no more than a few brief abstracts from the remarks made by speakers in the somewhat lively discussion that followed the reading of the main papers. Dr. Julian Huxley pointed out that there are two main trends of thought : that accepting phylogenetic facts or inferences as the basis of taxonomy, and that contending that classification should be based on correlation of characters with the possibility of explaining the results of such classification phylogenetically. He did not think the two points of view are irreconcilable. Dr. W. B. Turrill considered that much so-called phylogeny is, for the Angiosperms, pseudo-phylogeny. He particularly emphasized the danger of including phylogenetic facts or assumptions, however concealed, in a classification if that classification is later to be used as furnishing proof for a given phylogenetic scheme. Sir William Wright Smith was convinced that it is impossible to establish a phylogenetic system for plants that can be more than highly speculative, in the absence of relevant fossil evidence.

Dr. R. Melville stated that the papers and discussion showed the need for a thorough revision of the logical basis of both taxonomy and phylogeny. Mr. B. L. Burtt said that Dr. Sprague claimed no more than that taxonomic groups are monophyletic, members of a logically 'natural' group being of common origin. A phylogenetic classification does not seem possible in the absence of fossil evidence. Dr. J. Burtt Davy said that in teaching taxonomy a phylogenetic basis is a great help. Mr. M. J. D. White said that it is evident that very different points of view are held by those who work with different groups of organisms. He believed that cyto-genetics will have much to contribute to the subject in the future. The president (Dr. J. Ramsbottom) said, in closing the discussion, that in the fungi the fossil evidence is quite unreliable and that the so-called phylogenetic trees from time to time published for this group are based on such superficial evidence as to be sheer nonsense.

RELATIONSHIPS OF THE FUCALES

AS recently as 1937 Kylin expressed the view that the Fucales occupy an isolated position and have not been derived from the Phæosporeæ. Dr. M. Delf has reviewed the basis for this conception in the light of recent work on the higher Ectocarpales (*New Phyt.*, 38 ; 1939) and shows that Kylin's view cannot be too easily accepted.

The apical growth, which has been regarded as a difficulty in relating the Fucales to the Ectocarpales, has been shown by Nienburg to be preceded in the sporeling by an apical tuft of hairs, and the apical cell is derived from the basal cell of the intercalary growing zone of one of these. A rather similar development of conceptacles and cryptostomata in Fucales from growth originating from the base of a hair has some resemblance with the slightly sunken tufts of hairs of Colpomenia, Leathesia, etc.

The problem of the differences in ciliation of motile cells, the longer cilium, anterior in Fucus, usually posterior in Ectocarpales, seems a point of doubtful value and apparently liable to greater variation than was formerly realized.

Dr. Delf points out that the structure of the Fucus thallus could be derived from such a type as Eudesme, as described by Parke. She suggests that in place of the alternation of generations shown by the higher Ectocarpales, the Fucales have developed a perennial macrosporophyte and, possibly associated with adaptation to the intertidal zone, the gametophyte has suffered extreme reduction. It is of interest in this connexion that the Fucales of warmer waters remain submerged, and in Cystoseira and Sargassum, etc., the contents of the oogonium may be extruded in the 8-nucleate condition, which is in effect equivalent to a small haploid gametophyte, and from this the single oosphere is derived by degeneration of the remaining nuclei.

SEVENTY YEARS AGO

NATURE, vol. 1, April 21, 1870

Experimental Research and Unemployment

AN essay by George Gore, F.R.S., entitled "On Original Experimental Research in Relation to Employment for Workmen", shows that the struggle for recognition of the significance of scientific discovery for social progress had already begun.

"The variety and extent of the employments which have resulted from scientific research are so great that they ramify in some form or other through nearly all our manufacturing, artistic, and commercial occupations, our social relations, and our everyday life. . . . In many instances the application of original experimental science in new inventions had superseded, and in a limited sense diminished, manual labour, but it has in such cases either substituted more intellectual occupation for it, or has opened up new sources of employment to a far greater extent by increasing trade and manufacture. . . .

"The extension of physical and chemical knowledge by means of experiments and observations is *national* work : it benefits the nation, but does not pay the investigator. . . . Has it been wise in our Governments thus to overlook a great source of the nation's wealth, to disregard a most important means of national economy, to neglect the great fountain-head of industry ?"

Channel Railways

THE third of the series of articles on direct communication with France across the English Channel appears. It is devoted to discussion of "submerged roadways" or "tubes" of iron or concrete constructed on the sea bed.

Among the designs considered is that due to the late Mr. Chalmers, who proposed to have a gigantic tower or ventilator in mid-Channel, to which would be attached 400 ft. lengths of wrought-iron tube floated into position and drawn down by chains to the sea bottom.

Another scheme, considered in more detail, is that of Messrs. Bateman and Révy, who propose to lay a cast-iron tube on the sea bottom, starting from one shore and building it up inside a horizontal bell or chamber which is being constantly pushed forward. The tube would consist of cast-iron plates 4 in. thick lined with brick in cement, and carried on screw piles ; its inside diameter when completed would be 13 ft. The propulsive power for trains in such a tube would be pneumatic ; that is, the trains would be propelled by air forced into the tunnel by powerful pumps of large capacity in the form of gasometers.

ACCORDING to the *Photographic News*, the oft-reiterated statement that the eye of a dead animal has impressed upon it an image of the last object seen in life has been the subject of serious investigation in Germany. Americans have gone so far as to state that the eye of a murdered man had been found in which a portrait of the murderer was distinctly traceable. In the investigation in question the eyes of thirty different animals, all of which had been killed with a view to subsequent examination, were carefully inspected, but in no case was there any evidence discovered to warrant the statement referred to.

FORTHCOMING EVENTS

Saturday, April 20

Association of Scientific Workers (at the Guild of Undergraduates Union, Birmingham), at 3 p.m.—Conference of Industrial Scientists. (Speakers: J. S. Hunter: "Salaries, Cost-of-Living Adjustments, Overtime"; Dr. C. J. Milner: "Holidays and the Five-day Week"; J. Skeel: "The Problems of Assistants, (*a*) General and Economic Problems"; A. G. Ward: "The Problems of Assistants, (*b*) Problems of Technical Education": Dr. R. E. Priestley: "Science as a Reserved Occupation".

Tuesday, April 23

Institution of Electrical Engineers (Wireless Section), at 6 p.m.—Discussion on "War-Time Standardisation" (to be opened by P. R. Coursey).

Thursday, April 25

Institution of Electrical Engineers, at 6 p.m.—Dr. C. G. Darwin, F.R.S.: "Thermodynamics and the Coldest Temperatures" (Thirty-first Kelvin Lecture).

Friday, April 26

Royal Institution, at 9 p.m.—Dr. E. C. Bullard: "The Geophysical Study of Submarine Geology".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Borough Electrical Engineer and General Manager—The Town Clerk, Guildhall, Oswestry (April 26).

Principal of the Burnley Municipal College—The Director of Education, Education Offices, Burnley (April 26).

Lecturer in the Department of Pure and Applied Science—The Registrar, Loughborough College, Loughborough (April 27).

Assistant Livestock Expert for Animal Husbandry work in Bengal—The High Commissioner for India, General Department, India House, Aldwych, W.C.2 (quoting Appointment 9/2F) (April 27).

Male Teacher of English for British Institute, Genoa—The British Council, 3 Hanover Street, W.1 (quoting 'Italy') (April 27).

University Graduate as Teacher of English for British-Peruvian Cultural Association, Lima, Peru—The British Council, 3 Hanover Street, W.1 (quoting 'Lima') (April 30).

Temporary Adviser (male or female) in Horticulture—The Agricultural Organizer, Berkeley House, Berkeley Street, Gloucester (April 30).

Principal of the Ceylon University College—The Director of Recruitment (Colonial Service), Colonial Office, 29 Queen Anne's Gate, S.W.1 (April 30).

Assistant Lecturer in Geography—The Registrar, University, Manchester 13 (May 1).

Headmaster of Alleyn's School—The Clerk to the Governors, Dulwich College, S.E.21 (May 3).

Lecturer in Sinhalese—The Secretary, School of Oriental and African Studies (University of London), at Christ's College, Cambridge (July 1).

Assistant Engineer for the Public Works Department of the Government of Nyasaland—The Crown Agents for the Colonies, 4 Millbank, S.W.1 (quoting M/9202).

RESEARCH AND INVENTION IN UNIVERSITIES

UNIVERSITY authorities have for many years encouraged their staffs and students to do research work, the principal reason, especially applicable to the students, probably being that research is excellent educational training and therefore falls within the sphere of the primary activity of universities. A secondary reason, especially applicable to the staffs, is that research may produce results of great public benefit and is, to that extent, not inconsistent with the reason for existence of universities.

Research is, however, costly, and university authorities are not usually provided with funds on which there are not other demands, so that it becomes necessary either to obtain additional financial support or to limit the research. Although all kinds of research tend to grade into one another, it can be roughly divided into two classes, 'pure' research and 'applied' research, as is indeed indicated in the title of the "Department of Scientific and Industrial Research". While the mere publication of the results of any research may be of great public benefit, the direct financial reward thus obtained either by the research worker or by the university authorities is almost negligible. 'Pure' or 'scientific' research, however, differs from 'applied' or 'industrial' research, in that while there is no ready method of obtaining a direct financial reward for the results of pure or scientific research, applied or industrial research can generally be given a direct financial reward by means of the grant of a patent. A patent is granted for "any manner of new manufacture" in Great Britain, and, by enabling the patentee to prevent anyone else from using what is patented, confers on him the power to sell the right to manufacture it to any industrial organization willing to do so. By using the patent system in this way for the results of applied or industrial research, research workers and university authorities are able to obtain direct financial support from industrial organizations additional to any financial assistance given by Government or obtained in other ways. In all the great industrial countries, research workers and university authorities use their patent systems in this way, and the financial support thus obtained provides funds for the further encouragement of both classes of research. The methods by which different countries use their patent systems, however, have developed in different directions.

In Great Britain, university authorities have in general developed a method by which a professor is left entirely free to guide the research of his subordinate staff and the students under his care in the direction that he thinks best. He may feel that research in some particular line will give the students the best educational training or will afford the staff the best opportunity of conferring some public benefit, but in general he is left free to determine what, if any, use he will make of the patent system on the results of the research. Some professors merely publish the results made under their direction, while others take care to patent such results as seem likely to bring direct financial reward. In the former case the professor may feel that all the results of research should be freely dedicated to the public, and he may have, on this ground, an ethical objection to patenting any results. In the case of a professor who patents such results as seem likely to bring direct financial reward he may feel that by so doing he is ensuring that the greatest public benefit will be obtained, because, as is frequently pointed out, results of research dedicated to the public merely by publication are often most effectively withheld from the public since no one will assume the business risk and the development expense necessary to commercialize an article over which he can have no control for a reasonable period. If these results of applied or industrial research are patented, there is often an arrangement between the professor and some industrial organization giving the organization first claim on the commercial exploitation of the results in return for some financial reward and in some cases benefaction to the university.

The development in the universities in the United States of their methods of using their patent system was indicated recently by Mr. A. A. Potter, of Purdue University, in his address on "Research and Invention in Engineering Colleges" as vice-president of the Engineering Section of the American Association for the Advancement of Science. In preparing his address Mr. Potter states that he obtained information from thirty-nine universities and colleges, of which seven had organized research foundations for administering desirable patent policies, three others had entrusted the handling of their patent matters to the Research Corporation of New York, two others had given the responsibility for patent administration to a State board, and thirteen others had formed committees or boards to deal with their patent policies. About two thirds of the universities and colleges consulted had definite patent policies and these, it is pointed out, were the universities and colleges that received the greatest support from industry. Mr. Potter reports that "those Universities and Colleges which have definite patent policies are of the opinion that both the social and economic welfare of the public are being enhanced by their methods of handling patents and of encouraging creative activity of their staff members." In his opinion there is a definite trend for universities "to set up research foundations of their own, which finance research and to which the inventor assigns all rights of his research findings. Such institutional research foundations are non-profit corporations organized for the purpose of encouraging creative talent by relieving the inventor of the financial burden and loss of time from his research interests, and by financing research from profits accruing from the sale or royalty on patents."

In Germany, the policies of the universities with regard to patents have been generally more nearly allied to those of British universities rather than to those of American universities.

The great difference between the methods of using their patent systems developed in the American universities and in British universities is remarkable, when the similarity between their ideals is borne in mind. Whatever causes have contributed to this difference and however suited to the American mind may be the policies of their universities, it is certain that the policies of British universities are more suited to the character of the British people than would be the policies of the American universities. The personal freedom and the direct responsibility which the policies of British universities in general confer on their professors are characteristics which are not found to the same extent in American universities and which we should be loath to lose.

These characteristics, although general in British universities, are not universal, for in some cases British research workers are severely discouraged from patenting the results of their research—not infrequently with unfortunate consequences to themselves and the universities. A more tolerant attitude towards the British patent system, for example, by the controlling authorities in the research by British workers on the use of ultraviolet rays in preparing anti-rachitic products of foods and medicines, would undoubtedly have resulted in much greater credit being accorded to British research workers and in thousands of pounds being received by Great Britain from all parts of the world instead of being sent from this and other countries to the United States, as has, in fact, been the case ; and this is only one example of many.

It may well be that the safest course to follow in all research of which the results are likely to be of applied or industrial use is that the research worker should be free to apply for patent protection immediately he obtains his results, and should be encouraged to do so. If the results are of no commercial use little or no harm is done, but if they can be exploited commercially some industrial organization will place them on the market and so make them available to the public, the research worker will be given the credit of his results, and the beneficial owner of the patent, whether it be the research worker, the university, or others by contractual arrangement with them, will reap the financial reward.

NATURE IN THE CLASSICS

Nature in Greek Poetry
Studies partly Comparative. By Dr. George Soutar. (Published for St. Andrews University.) Pp. xix+258. (London: Oxford University Press, 1939.) 10*s*. 6*d*. net.

THE University of St. Andrews, which offered us three years ago the second and more complete edition of the monumental "Glossary of Greek Birds", by Sir D'Arcy Thompson (which I had the privilege to review in these columns), presents now to the lovers of classic literature another important work, by the late Dr. George Soutar.

Mr. J. C. Smith contributes a long biographical notice on the author. George Soutar entered the University of St. Andrews with a University Endowments Association bursary, which he bettered next year by winning a Bruce bursary. At college as at school his favourite subjects were English and Greek, and he was fortunate in his professors, Thomas Spencer Baynes and Lewis Campbell. Mathematics afflicted him, but in the humanities he proved one of the best men of his year: he was first in rhetoric and second in logic, Latin and Greek, and crowned his career in 1888 by graduating with first-class honours in classics. He won a prize for a poem on "Immortality", and this was not his only adventure in verse. St. Andrews gave him something even better than book-learning and the cultivation of the Muse; its small and friendly society gave a unique opportunity to his genius of friendship. His appointment as external examiner in English in 1896 made another link with St. Andrews for Soutar, and the connexion became permanent when in 1907 he was appointed to the staff of University College, Dundee, where, first as lecturer and after 1927 as reader in English, he served the University, until he retired in 1935. The official connexion did not end even then, for the University showed its gratitude by appointing him external examiner in English for a second time—an unusual compliment. The Senate designed yet another honour for him; they meant to present to him at the 1939 graduation the degree of LL.D.; but his death in February of that year frustrated their intention.

Soutar's students knew his great gifts as a teacher, but he published very little. The volume of selections from Pope and a "Book of Ballads", in collaboration with Mr. J. C. Smith, were all the books that appeared in his lifetime, although he also contributed two articles on Sir George Mackenzie and one on "Scot or Wyatt?" to the *Scots Magazine*. The present volume, the manuscript of which he left behind him, was his thesis for the doctorate of letters. He worked over it at intervals for a long time and until his death, remodelling it and enriching it as his knowledge of literature increased. Perhaps, we may assume, a few parts of the book waited for a finishing polish from the elegant pen of the author.

It is generally thought, and not without good reason, that classics of the purest period are not very keen about Nature, and, anyhow, that their rather short and occasional descriptions of Nature have an epigrammatic character.[*] They are mainly used, as, for example, by Homer, in comparisons with aspects of human life. So the famous image in the "Iliad":

> "The race of man is of the race of leaves:
> Of leaves, one generation by the wind
> Is scatter'd on the earth; another soon
> In spring's luxuriant verdure bursts to light.
> So with our race; these flourish, those decay."

Or the other lines, also from the "Iliad", the beauty of which ranks among the jewels of classical poetry:

> "As when in Heav'n, around the glitt'ring moon
> The stars shine bright amid the breathless air;
> And ev'ry crag, and ev'ry jutting peak
> Stands boldly forth, and ev'ry forest glade;
> Ev'n to the gates of Heav'n is open'd wide
> The boundless sky; shines each particular star
> Distinct; joy fills the gazing shepherd's heart.
> So bright, so thickly scatter'd o'er the plain,
> Before the walls of Troy, between the ships
> And Xanthus' stream, the Trojan watchfires
> blaz'd."

Homer's indifference to Nature is shown also, as Dr. Soutar remarks, by his lack of flower-sense. Although flowers are one of the outstanding beauties of Nature, not a single epithet of form or of colour is attached by him to any flower. Calypso's violets, the single and only mention of which in Homer makes Dr. Soutar exultant, are left uncharacterized by the poet. Crocuses and hyacinths form merely a bed "thick" and "soft"—πυκνὸν καὶ μαλακὸν. Homer makes no allusion to the fragrance of flowers. They are not spoken of sentimentally as associated with human joy or sorrow, not regarded as significant symbols.

---

[*] Under the term "epigrammatic", I include all descriptive adjectives attributed by Homer to the sea, mountains, rivers or other natural features. Such epithets as "wine-dark" for the sea; "shadowy" for mountains; "deep-eddying", or "beautifully-flowing", for rivers; and "starry" for the firmament; all of them give but a flashing glimpse of the object, they do not constitute descriptions in the strict sense of the word.

Dr. Soutar consoles himself for this lack of flower-sense in Homer when he finds in the "Odyssey" (Book VII, 112–113) the luxurious description of King Alcinoüs' garden at the side of his palace. He gives a translation of his own of the passage, in prose, but I prefer to quote it here in the lines of Cowper:

"A spacious garden lay, fenced all around
Secure, four acres measuring complete.
There grew luxuriant many a lofty tree,
Pomegranate, pear, the apple blushing bright,
The honied fig, and unctuous olive smooth.
Those fruits, nor winter's cold nor summer's heat
Fear ever, fail not, wither not, but hang
Perennial, whose unceasing zephyr breathes
Gently on all, enlarging these, and those
Maturing genial; in an endless course
Pears after pears to full dimensions swell,
Figs follow figs, grapes clust'ring grow again
Where clusters grew, and (ev'ry apple stript)
The boughs soon tempt the gath'rer as before.
There too, well-rooted, and of fruit profuse,
His vineyard grows; part wide-extended, basks,
In the sun's beams; the arid level glows;
In part they gather, and in part they tread
The wine-press, while, before the eye, the grapes
Here put their blossom forth, there gather fast
Their blackness. On the garden's verge extreme
Flow'rs of all hues smile all the year, arranged
With neatest art judicious, and amid
The lovely scene two fountains welling forth,
One visits, into ev'ry part diffus'd,
The garden-ground, the other soft beneath
The threshold steals into the palace-court,
Whence ev'ry citizen his vase supplies.
Such were the ample blessings on the house
Of King Alcinoüs by the Gods bestow'd."

Unfortunately, this description is considered as spurious, a mere interpolation by a writer much more modern than the Homeric era, and of a period when romanticism invaded literature, superseding the naked simplicity of classical poetry, and it indulged in mellifluous evocations. As a matter of fact, it is remarked by one of the most learned commentators and editors of the "Odyssey", the late Victor Berard, that the existence of such a large garden, occupying an entire acre (because Cowper is mistaken in his translation of the Homeric area as implying four acres), in which the royal palace was situated is impossible. The excavations at Mycenae, Tiryns and elsewhere, prove convincingly that the enclosures containing the royal mansions, though strong enough for protection, were too small for a garden and orchard as described in the above lines.

Still, Dr. Soutar could stick for a genuine description of Nature in Homer to the few lovely lines in which his beloved, though uncharacterized violet flourished. May I be allowed to quote it here, again from Cowper's translation of the "Odyssey" (Book V, 68–74):

". . . a grove on either side,
Alder and poplar, and the redolent branch
Wide-spread of Cypress, skirted dark the cave.
There many a bird of broadest pinion built
Secure her nest, the owl, the kite, and daw
Long-tongued, frequenter of the sandy shores.
A garden-vine luxuriant on all sides
Mantled the spacious cavern, cluster hung
Profuse; four fountains of serenest lymph
Their sinuous course pursuing side by side,
Stray'd all around, and ev'ry where appear'd
Meadows of softest verdure, purpled o'er
With violets; it was a scene to fill
A God from Heav'n with wonder and delight."

Leaving Homer, Dr. Soutar proceeds to the study of other poets. The Hesiodic poems, he says, are almost destitute of flowers. They are only mentioned in the garland put by Athena on the head of the maiden, "the beautiful evil" formed by Hephæstus ("Theog.", 576). Still this is not a description of Nature but only of an ornament. Archilochus is the first to mention "the fair flower of the rose-bush"—ῥοδῆς τε καλὸν ἄνθος, but the mere mention of the rose, with the simple epithet *kalon* (pretty), does not show, I think, much enthusiasm for the queen of flowers. We must reach the era of decadent poets of the "Anthology" and to Anacreon to find praise worthy of the subject. The epithet ἰοστέφανος, so well known later, is applied to Aphrodite in Solon and to the Muses in Theognis. To find something specifically and purely connected with flowers, Dr. Soutar rightly has recourse to the lovely choral song in "Œdipus at Colonus", where Sophocles extols the wooded hill near Athens:

"Thou hast come to a steed-famed land for rest,
 O stranger worn with toil,
To a land of all lands the goodliest
 Colonus' glistening soil.
'Tis the haunt of the clear-voiced nightingale,
 Who hid in her bower, among
The wine-dark ivy that wreathes the vale,
 Trilleth her ceaseless song;
And she loves, where the clustering berries nod
 O'er a sunless, windless glade,
The spot by no mortal footstep trod,
 The pleasance kept for the Bacchic god,
Where he holds each night his revels wild
With the nymphs who fostered the lusty child.

"And fed each morn by the pearly dew
 The starred narcissi shine,
And a wreath with the crocus' golden hue
 For the Mother and Daughter twine.
And never the sleepless fountains cease
 That feed Cephisus' stream,
But they swell earth's bosom with quick increase,
 And their wave hath a crystal gleam.
And the Muses' quire will never disdain
To visit this heaven-favoured plain,
Nor the Cyprian queen of the golden rein."

Another early classical fragment, the famous tetrastich by Sappho, in which the poetess laments her lonely night, is quoted too by Dr. Soutar as a description of nocturnal skies, when moon and Pleiads are set, as an evocation of Nature. But let us read the poem in the high-sounding music of its Doric idiom and we will see that it has little to do with moonlight and stars and much more with the despair of a soul—the incandescent soul of the poetess. Here is its rendering, but how inferior it looks to the original, how cold it is to the flame burning throughout the Greek lines :

> "The moon is gone—And the Pleiads set,
> midnight is nigh—Time passes on, and passes—
> yet alone I lie down."

Those who can read Greek must take and recite the original aloud.* They will realize then the inimitable beauty of these four lines crying the desolation of a heart, insatiable of exaltation.

In spite of other examples and ample quotations in the book, the impression persists that mere descriptions of Nature and for the sake of Nature itself are rare in earlier and purely classical poets. The love of Nature instead becomes a more general feeling among post-classical poetry. There are striking examples of it, such as the lovely poem to the Cicala from Anacreon (which it should not be forgotten is the composition of some Alexandrian imitators, as Anacreon's work itself is entirely lost to us), with its charming first ten tines :

> "Drunken with a drop of dew,
> Happy, happy as a king,
> We can hear thee twittering ;
> Everything within thy view
> From the tree-top, in the fields,
> Everything each season yields,
> O cicala, is thy dower ;
> Dear to everyone thou art,
> Dearest to the farmer's heart,
> Prophet sweet of summer's hour !"

Instead, I do not really find descriptions of Nature in some translations from Greek poetry printed at the beginning of the book. The "Fishermen", from Theocritus, the fragments from the Second "Olympian" Ode of Pindar, an unspecified fragment from Euripides, and the "Lament for Adonis", from Bion, seem to have a rather remote connexion with Nature, and they are probably published here to show Dr. Soutar's ability for rhymed translations from the Greek, as in the absence of any contrary indication, I must presume that the rendering of these fragments are from his own pen.

If the chapter on the Greek anthology, which concludes the book, was not one of the two to which we understand the author had not the time to add the last touches, was to be adequately completed, how welcome would be in regard to the purpose of the book the reproduction of the charming description of the Grove by the River Iris, probably by Marianus Scholasticus, so felicitously rendered by A. J. Butler in his little volume "Amaranth and Asphodel" :

> "This is the grove of Love, whose leafy bowers
> Are rustling to the west-wind's gentle sound,
> Where all the dewy mead is set with flowers
> That lift their azure glory from the ground.
> Here from three ledges on the hillock springs
> A brook by fountain-nymphs shot down the glade,
> While through yon copse the ancient Iris swings,
> And soft-haired wood-nymphs court the noontide shade.
> Here goodly olives, here the clusters twine
> And hang their fruit above the sunny floor ;
> Around to warbling nightingales divine
> Cicalas quire and answering music pour.
> Enter my home and share my lowly cheer."

Here, indeed, "when the Hellene", according to Dr. Soutar's own happy expressions, "has become a Hellenist, and he has drunk of the wine of the Orient, he undergoes a change in feeling, colouring his conception of external Nature with a more sensuous and subjective treatment".

It is to be regretted that in such a scholarly book some not unimportant omissions occur. The occasional reader, for example, will look in vain for many of the Greek quotations to be followed by a translation. The reader, with even a moderate classical training or a remnant of reminiscences of his Greek studies, will enjoy such quotations even if he is compelled to consult from time to time his Liddell and Scott. The outsider, however, will stop in despair at many passages, wondering what they mean and to what extent the author is justified in quoting them as characteristic in the scope of his work. Other fragments are published only in their English translation, not rarely without the respective reference to the original. The lack of an index constitutes also a drawback, fortunately so rare in English books, which, treasured after a first reading, may be enjoyed again and again in hours of need of comfort or relaxation, when some particular passage has left in the memory a faint scent, which one loves to inhale once more.

In spite of such reservations as the above, I loved the book and enjoyed it immensely. Many readers in their turn will delight in the fragrance of the flowers of this *Florilegium*, gathered and arranged by an expert hand into a bouquet of beauty and charm.

The printing of the Oxford University Press is, as always, irreproachable.

Demetrius Caclamanos.

ROCK METAMORPHISM

Metamorphism.
A Study of the Transformations of Rock-Masses. By Dr. Alfred Harker. Second edition, revised. Pp. x + 362. (London: Methuen and Co., Ltd., 1939.) 21*s*. net.

THE first edition of this book appeared in 1932. Dr. Harker had completed the revision of the text of this second edition only a few weeks before his death, which took place in July 1939. The modifications appearing in the new edition are chiefly minor changes, usually limited to a few words each, leading to certain clarifications. In addition, references to some of the work which has appeared between 1932 and 1939 are given, but little new matter is incorporated in the text. Among the more important alterations are the following: the cordierite-anthophyllite rocks of Kenidjack, Cornwall, are now considered with Eskola's Orijarvi analogues in the chapter dealing with pneumatolysis and metasomatism; brief mention is made of recent experiments by Bridgman and Larsen on stress effects; the inhibition of reactions through the presence of carbonaceous material, a notion rather frowned upon in the first edition, is now admitted to be possible; there are certain additional remarks on the Inchbae aureole, adinoles, the oligoclase zone, eclogites, etc. The book thus remains essentially unchanged.

In its own field, Harker's "Metamorphism" is a masterpiece. It presents the essentially British contributions to the study of the metamorphic rocks, chief among these being Barrow's zonal work, and the notion of rock metamorphism as a series of progressive changes in response to changes of external conditions. Harker's presentation is reinforced by a wealth of personal observations and by perfect lucidity of expression. The book remains as a magnificent monument to Harker and his generation.

It is not ungenerous to suggest, however, that the field covered by Harker is a very restricted one, and that his outlook was essentially conservative. These facts should be realized by British students in particular, who should take this book as a partial and personal statement. There are wide realms of investigation in metamorphism that were scarcely touched upon by Harker. Such topics as migmatization and its relation to metamorphism, petrofabrics, the importance of metasomatic processes and so forth are not dealt with, and yet it is along these lines that future progress in the study of British metamorphic rocks is likely to develop. Once the limitations of Harker's treatment are realized, however, his work can be used as a sure foundation for British metamorphic geology—a foundation not possessed by field-workers in other countries. Upon this firm base can be built all the more securely the future edifice of British contributions to the development of metamorphic studies.

THE CHEMICAL BOND

The Nature of the Chemical Bond and the Structure of Molecules and Crystals
An Introduction to Modern Structural Chemistry. By Prof. Linus Pauling. (The George Fisher Baker Non-resident Lectureship in Chemistry at Cornell University.) Pp. xiv + 429. (Ithaca, N.Y.: Cornell University Press; London: Oxford University Press, 1939.) 21*s*. net.

SINCE G. N. Lewis's fundamental paper of 1916, the electronic theory of valency has been amplified and applied so extensively as to create the need for a monograph every few years; and every few years, so far, a monograph has been produced by a leading contributor to the subject. Lewis's own book "Valence and the Structure of Atoms and Molecules" (1923), Sidgwick's "Electronic Theory of Valency" (1927), and his "Covalent Link in Chemistry" (1933), set a high standard, and the present volume is a worthy successor.

In it the author discusses the nature of chemical combination in both molecules and crystalline aggregates. The treatment is based on the electronic theory of valency as rationalized and extended by quantum mechanics, special emphasis being laid on the resonance phenomenon. The fundamental types of combination are discussed very thoroughly. The one-, two-, and three-electron bonds are considered as involving resonance between alternative electron assignments among the bonded atoms. The directed bonds in polyvalent atoms involve additional resonance among the *s*- and *p*- or *s*-, *p*- and *d*-orbitals of the polyvalent atom. Bonds of partially ionic character are represented as resonance between electron assignments corresponding to electrostatic and co-valent (2-electron) bonds. Metallic bonds are described in terms of resonance between alternative positions for one- and two-electron bonds. Finally, the specially important case of "resonance of molecules among several valence bond structures" (or mesomerism) is described and extensively illustrated.

No mathematics is introduced, conclusions which can be justified or made plausible only by arguments more or less mathematical in nature being stated without proof. The method of treatment is an excellent one for enabling much ground to be covered in a short space, and is a procedure that is wholly justified for the author, who (with E. B. Wilson) has already produced a first-class text of chemical quantum mechanics; but the reviewer hopes that a study of the more cursory treatment in the present text will not be regarded as an adequate alternative to an acquaintance with the elementary ideas of quantum mechanics as a foundation for the theory of the atom and of valency. More might have been written, for example, of the subjective nature of resonance, as shown by the general character of the variation theorem, or, more remotely, by the subjective aspect of much of quantal philosophy. The difficulties illustrated would be cured if readers of the book could be persuaded to read Prof. Pauling's other book, and his original papers, especially those which form the basis of the present work and were published under an identical title.

On the experimental side, one of the most valuable features of this work is the large extent to which it co-ordinates the mass of information that has in recent years accrued from the various physical methods of investigating molecular structure. The tables of ionic radii, bond lengths, valency angles, bond energies, etc., alone would be important, but they are made much more so by the synthetic and suggestive manner in which they are presented and discussed. Alike in this field and in the theory, the book is in large measure a record of Prof. Pauling's personal contributions, and it will be assured of as permanent a place as its three predecessors in the contemporary history of chemical science.

C. K. Ingold.

THE STUDY OF HANDWRITING

Analysis of Handwriting
An Introduction into Scientific Graphology. By H. J. Jacoby. Pp. 286+27 plates. (London: George Allen and Unwin, Ltd., 1939.) 10*s*. 6*d*. net.

HANDWRITING is obviously a form of individual expression by hand gesture; no two children who have been taught to write from the same copy and even by the same teacher will ultimately develop identical handwritings. The differences in handwriting must, therefore, be due to personal characteristics—manual, æsthetic, emotional or intellectual—of the writers themselves.

The author makes no attempt to investigate the pictographic origin of writing, or to link it to other forms of expression by gesture, or with precision (or the reverse) in articulation—with which, in particular, handwriting might be expected to be associated. He claims that handwriting is significant of the writer's "general manner of working". But this, though possibly true as to craftsmanship, might not be true of other forms of work. Some very able individuals are notoriously 'butter-fingered'.

Many of the author's conclusions will be readily accepted, for example, that in handwriting, good spacing and regularity indicate orderliness and self-discipline: that exaggeratedly large writing denotes love of display, and that small and precise handwriting implies an unemotional or pedantic nature. Other dicta, such as that convex curves (arcades) indicate "shutting to the outside world", or that movements to the right manifest tendency towards the outside world (and *vice versa*) need further proof.

The book would be easier to read if the 161 illustrations—which are well reproduced—were more systematically related to the descriptive text. Fewer illustrations, more carefully chosen, would have been better. The index, too, could have been improved by additional headings.

The author claims for 'graphology' a high percentage (87–95 per cent) of correct judgments as to character, psychological condition, ability, etc. To check this claim, the Institute of Industrial Psychology, for example, might provide Mr. Jacoby with specimens of the handwriting of a number of cases examined by them, so that the correlation between the findings of graphology and of psychological analysis might be measured.

This book is certainly interesting, though somewhat discursively written.

R. A. S. Paget.

INFRA-RED SPECTRA AND THE STRUCTURE OF MOLECULES*

BY DR. W. H. J. CHILDS AND DR. H. A. JAHN,
ROYAL INSTITUTION, LONDON

WE have to go back only to 1800, to W. Herschel's discovery that beyond the red end of the sun's prismatic spectrum there is something capable of warming the bulb of a thermometer, to find the germ of a method which, through its contributions to our knowledge of molecular structure, is beginning to be of much importance both to chemistry and to physics. Herschel's discovery was accompanied by an error—that the energy maximum of the spectrum lay also outside the red—though this probably made it even more effective in stimulating the curiosity and imagination of contemporary men of science. In spite of this interest, for the rest of the century progress was slow, and this period is taken up first with the need of proving that the new rays are nothing other than invisible light and obey exactly the same laws; and then with the task of mapping the new region, to find out if and how the radiation is absorbed by matter.

On looking back, we see that the real advances are the improvements in technique, mainly concerned with increasing the sensitivity of radiation detectors. Towering above all in its effect was the discovery by Rowland of a method of making a perfect screw, and with it constructing the concave diffraction grating. These technical advances have made their permanent impression, and we find to-day that the thermopile and the diffraction grating in their modern improved forms are playing a leading part in infra-red research. At the beginning of the twentieth century, though many absorption spectra in the region 1–20 μ had been measured and it was known that every substance, with the exception of the diatomic homopolar molecules such as hydrogen and nitrogen had characteristic absorption bands in the infra-red, no success had attended the few attempts empirically to systematize this knowledge. Indeed it is only in recent years, following upon the successful disentangling of the spectra of diatomic molecules with the help of quantum theory, that infra-red absorption bands are being related to other molecular magnitudes.

The starting point of the theoretical interpretation of infra-red molecular absorption bands is the Faraday-Maxwell electromagnetic theory of radiation. Once it was clear that radiation consists of electrical oscillations, the absorption of infra-red radiation by molecules could be explained on the basis of resonance between the electrical oscillations of the individual molecules and the oscillations of the electromagnetic field. The occurrence of characteristic frequencies in the absorption spectrum pointed to the existence of a definite spectrum of frequencies possessed by, and characteristic of, each individual molecule, this again pointing to a definite mass distribution and force system in the molecule.

Before Rutherford's nuclear theory of the atom, however, very vague ideas were current about the distribution of mass in the molecule. Molecules were considered to be built up of spherical ions, and characteristic frequencies of the individual ions were often spoken of, as would be possible if there were a characteristic distribution of mass in the ion itself. With the advent of Rutherford's theory, the distinction was quickly made between electronic frequencies involving the electronic mass, and the much slower frequencies involving the nuclear masses. It is these latter frequencies which show up in the infra-red absorption bands. Thus, for example, the water molecule is to be regarded as consisting of three heavy mass points held together in their equilibrium positions by electrical forces. It is easy to see that such a mechanical system possesses three degrees of vibrational freedom, so that the water molecule should have (as is indeed the case) three different molecular frequencies showing up in its absorption spectrum. It was this clarification of the situation that enabled Bjerrum in 1914 to lay the foundations of the method of calculating molecular frequencies still in use to-day. It had been pointed out still earlier by Lord Rayleigh that if the electrical oscillations have definite fixed directions in the molecule, then the rotational frequencies of the molecule will also appear in the spectrum, since the carrying round of the fixed electrical oscillation by the molecule will be equivalent to a harmonic oscillation having the same period as the molecular rotation, which will thus appear combined with the vibrational frequencies in the spectrum.

For the purposes of review, we may conveniently separate infra-red spectrographs into two classes, low resolving power prism and high resolving power grating instruments. The prism spectrograph is adequate to measure band envelopes, but for the finer structure due to molecular rotation, and to separate overlapping bands in the 3 μ region, and above all for work in the very long wave infra-red in the region 30–100 μ, a grating instrument is essential. Thus these two classes, very broadly speaking, give us respectively information about molecular forces and molecular sizes. The prism spectrograph has usually a theoretical resolving power of some few hundreds, but this is reduced when in use (the need of using slits wider than the optimum is one reason) by a factor of from four to eight. There have been advances in design in recent years. Careful placing of the entrance and exit mirrors of the prism, so that the errors introduced into the beam by one are partially rectified by the other, has resulted in much improved definition in the spectrum falling on the exit slit. There is a noticeable tendency to place the whole spectrograph in an evacuated chamber, thus avoiding the loss of energy in those regions of the spectrum where strong absorption by the water vapour and carbon dioxide of the atmosphere occurs. For the prism and windows we are no longer dependent on natural crystals of rocksalt, as large enough crystals can now be grown from the melt. Crystalline potassium bromide obtained in this way has extended the range of prism instruments to nearly 30 μ.

---

*Substance of a course of seven lectures delivered at the Royal Institution between November 3 and December 15, 1939.

Subsidiary apparatus has also been improved. Thermopiles with only one or two elements are constructed to have a resistance and speed of response to match the galvanometers with which they are to be used. The moving-magnet galvanometer has gone quite out of favour, and is replaced by a less sensitive but far more stable moving-coil instrument, connected by some form of photoelectric or thermo-electric amplifier to a second more rugged galvanometer from which the readings are taken. In some instances where careful design and construction have almost entirely eliminated disturbances and drifts, it has proved worth while to instal an automatic recorder.

With grating instruments the resolving power is usually of the order of several thousands, and although in practice the necessity of using slits wider than the optimum again sets the limit, nevertheless powers of 10,000 at 3 μ, and 300 at 80 μ, have been attained. The predominant type of grating is the 'echelette', with a predetermined groove-form to diffract the bulk of the energy in one particular direction. This property is a most desirable one, for the energy available is usually so meagre that its dissipation into spectra of more than one order cannot be tolerated. If it is desired to work in more than one region, several gratings must be employed, those for the longer wave-lengths having correspondingly wider grooves and thus, for the same resolving power, greater dimensions. Excellent gratings as large as ten inches by twenty inches have been produced for work at the longest wave-lengths, around 80 μ. The suppression of other orders and the scattered radiation of the more abundant shorter wave-lengths around 3 μ, which would so to speak 'fog' the thermopile, is achieved with judiciously selected filters, or by making use of selective *reststrahlen* reflections, or by a combination of both.

By using vacuum thermopiles, carefully screened conductors and evacuated spectrographs, disturbances and drifts are reduced to a minimum, but even so, automatic recording is not possible in the longer wave-length regions unless a special tuned amplifier is used. With this ingenious device the beam of infra-red radiation is interrupted periodically by a shutter so that the deflection of the primary galvanometer is also periodic. The amplifier is tuned to the same frequency and is thus insensitive to drifts and all disturbances of arbitrary period. The deflections of the secondary galvanometer may then be recorded photographically, since its zero remains steady.

It is possible to make measurements in the very short-wave infra-red, from the visible to 1·2 μ, with ordinary diffraction gratings and the specially sensitized photographic plates which are now commercially obtainable. The resolving power may be high, of the order of 20,000, but the relatively simple technique is unfortunately limited to a few types of bands of molecules containing hydrogen. In these cases alone is the absorption great enough to permit the use of absorption tubes of practical length.

The theoretical analysis of molecular infra-red absorption bands can be divided into two fairly distinct processes: the vibrational and the rotational analysis. This division follows quite closely the division of the experimental work into prism and grating spectroscopy respectively.

In the vibrational analysis we consider the molecule to be built up of point masses (the atomic nuclei) held together by elastic forces, and the major problem is to calculate the classical normal modes of vibration of such a system. Such a calculation necessitates a knowledge of the equilibrium configuration of the molecule and a knowledge of the elastic forces which are called into play when the atoms are displaced from their equilibrium positions. The geometrical configuration is usually fairly well established from chemical considerations or from the electron theory of valency, whilst the force system also in many cases goes hand in hand with the chemical formulæ. Thus a good part of the vibrational spectrum can be interpreted on the basis of characteristic stretching constants for the individual chemical bonds. A molecule possesses, however, in addition to such valency vibrations, deformation modes in which only the angles between chemical bonds change. It is tempting to introduce individual characteristic elastic constants for the angles between the bonds, but such a procedure is beset with pitfalls. A good example of the difficulties involved is the calculation of the deformation frequencies of the acetylene molecule. If a simple potential is assumed, involving only such characteristic angle constants, one obtains a false assignment of the fundamental frequencies which can only be avoided by taking into account a term in the potential energy which couples the two angle oscillators. The importance of such coupling terms has often been overlooked in calculations of the low-frequency fundamentals of molecules.

The calculation of the fundamental frequencies of even relatively simple molecules is a lengthy and tedious business, which can, however, be greatly shortened by making proper use of the symmetry of the equilibrium configuration of the molecule. There is further a general theorem due to Teller and to Redlich, which enables one to obtain useful results about the frequencies of isotopic molecules without making detailed calculations. This theorem is based on the fact that the vibrational or reduced mass of a normal mode can be expressed in the form of the product of the individual atomic masses divided by the total mass of the molecule and its moments of inertia, these latter entering only if the vibration has the same symmetry respectively as a translation or infinitesimal rotation of the molecule. Since an isotopic substitution of hydrogen by deuterium does not change the potential, the effect on the frequencies is determined solely by the change in the reduced mass. Thus from the form of the vibrational mass the ratio of the products of frequencies of isotopic molecules can be deduced. The agreement is never perfect, owing to the fact that the observed frequencies require correction for the anharmonicity of the vibrations, but this general product theorem has been of great value in checking the assignments of frequencies without making lengthy calculations.

The rotational analysis is a much more involved problem than the vibrational analysis. This is due not only to the fact that a definite spectrum of rotational frequencies is an idea quite foreign to classical theory and can be explained only on the basis of quantum kinematics, but also to the classical effect that internal vibrations in a rotating mechanical system give rise to Coriolis or vibrational-gyroscopic forces which greatly modify the rotational motion. The Coriolis forces as well as the simple centrifugal forces depend upon the nature of the vibrational potential, so that we obtain perturbations of the rotational structure of the absorption bands which depend upon the characteristic vibrational potential of the molecule. Thus whilst the simple theory of rigid rotating molecules leads to a classification of rotational spectra into those of spherical, symmetrical and asymmetrical top molecules, according to the nature of the ellipsoid of inertia, the exact theory requires a separate treatment for each individual molecule. A glance at recent work of this nature suffices to show that the quantum dynamical considerations involved are as thorough as any that have been necessary in the interpretation of the finer details of atomic theory. Whilst this complication might on one hand be regretted, it is on the other hand very satisfactory that the technical progress of experimental infra-red investigation has been so rapid that this branch of science will soon take equal rank with the sister science of atomic spectroscopy.

Although the advance in recent years has been so rapid, there is much more remaining to be done. The paucity of energy for wave-lengths greater than about 10 μ in the spectra of heated bodies has been a factor which from the very beginning has retarded development. The technique, like any other concerned with the measurement of small quantities, is a difficult one, so that even to-day, in spite of the great potential importance of measurements in the infra-red both to pure science and to industry, the number of schools engaged in breaking new ground is very small. To this situation must be added the neglect of the commercial instrument maker which, though natural enough in the circumstances, means that every worker who wishes to be abreast of developments must be something of a precision instrument maker as well. Any improvement in design or technique which would enable measurements to be made with the same speed, reliability and ease with which they are made with photographic spectrographs would be an advance of the first magnitude.

An attack in this direction which promises well is the evaporograph, in which the spectrum is received on the blackened face of an extremely thin celluloid film, the reverse face of which is covered by a layer of oil molecules in equilibrium with the vapour phase. The minute differences of temperature caused by the energy variations in the spectrum produce changes in the thickness of the oil layer, which show up when its interference pattern is photographed with blue or ultra-violet light.

In a review as short as this, applications can be only briefly indicated. For industry, important advantages are, first, that a sample may be examined without destroying or indeed interfering with it, and that very small quantities are required, and secondly, that since the spectrum between, let us say, 1 μ and 30 is a unique property of any given substance, that spectrum may in principle be used to identify the substance in any mixture in which it remains unaltered. In favourable cases concentrations as low as 1 in 10,000 may be recognized. If the substance is modified in the mixture, by association or otherwise, then its spectrum reflects the change and may be used as a source of information about it. So far as pure science is concerned, the greatest application of infra-red research in the near future will probably be made in conjunction with isotope chemistry, at first with deutero-substituted compounds, but later with other isotopes, carbon, nitrogen and oxygen in particular, as fast as they are made available in quantity. With this technique a knowledge of reaction mechanisms will be obtained which would scarcely be possible by any other method.

THE FENLAND*

By Prof. J. Stanley Gardiner, F.R.S.

THE Fenland is an area of 73 miles by 36 miles, covering 1306 square miles, and comprises parts of the counties of Lincoln, Norfolk, Suffolk, Cambridge, Huntingdon and Northampton. It consists of Jurassic clays underlying glacial boulder clay, cut into basins and water courses by tidal and river actions. Some Jurassic islands were left, such as Ely, while peat formed in the swamps to the south, merging into a broad belt of silt against the sea. The area was not stable, and peat and silt in places alternate ; and often horizons of submerged forests are followed by swamp conditions. In the earliest period of history the Fenland was a flat expanse with scattered islands and ridges from the surrounding uplands, all these cultivated, while the swamps yielded rough produce for stock, the streams abundant fish, especially eels, and the marshes wild-fowl. Of course it must have been a paradise to the Romans by providing an outlet for their energies, the results of which are problematical. It is only certain that there was wide cultivation succeeded by decay. This was possibly due to the neglect of drainage works, complicated by a small change in land-level in progress towards the termination of the Roman occupation.

In the Norman period the condition of the Fenland may be inferred from the map of the Domesday settlements. It must have been affected by the relatively recent monastic foundations of Crowland, Ely, Ramsay, Thorney and Chatteris. For his recently issued studies on the Fenland, Mr. Darby has consulted all authorities, but they have helped little as to the economy in this Anglo-Danish period. His inferences are based on the Domesday settlement—peat lands do not allow of the building of house foundations—the sizes of parishes and the distributions of fisheries, salt pans, meadow and other lands. The Wisbech estuary now became silted up and inundations followed. At some uncertain date the Eastern and Western Ouses were diverted, partly by artificial channels, to reach the sea at Lynn. Traffic to the surrounding lands apparently thronged the waterways. In the fourteenth century the Fenland was many times more prosperous than the surrounding upland. Strategically, it might be a centre of rebellion or of refuge—a comparison with part of southern Finland to-day is not inappropriate—but disturbances were largely dictated by neighbouring barons. Socially, there was no isolation and its people were not "endowed with any qualities of desperate wildness extracted by some mystical influence from reeds and rushes". Mr. Darby's economic study of this time is excellent, but he could have made it plainer to his readers had he presented a picture of the Fenland as it really was, its meandering rivers, open pools, marshes, sedge and litter lands, thickets and woods. Its peat is not the well-known product of moss but of the decay of sedge and litter ; it is very alkaline.

The account of Tudor times in the Fens reveals a woeful condition of dire poverty. This was partially due to the upheaval that succeeded the dissolution of the monasteries, but every 'Court' was quite ineffective in maintaining the Fenland channels and drains. Parliament became interested in the matter and in 1534 passed the first Act for the preservation of birds ; wild-fowl were given a close season in June, July and August, and the taking of their eggs was prohibited "upon pain of imprisonment for one year". Later, there were great floods and many permanent 'drownings', and in 1570 the sea broke in near Wisbech. Drainage thus became a matter of national rather than parochial interest, the first effort being concentrated on cleaning out the channels and repairing the banks near Wisbech.

The Draining of the Fens. By H. C. Darby. (Cambridge Studies in Economic History). Pp. xix+312+31 plates. (Cambridge: At the University Press, 1940). 21s. net.

The interest of King James resulted in a welter of ineffective activity. In 1630 the Earl of Bedford 'adventured' his money to drain the southern fens, now known as the Bedford Level. He employed that Vermuyden whom the Commissioners had previously refused to employ. His plan was to shorten the courses of the main streams so as to increase their gradients, erecting the necessary sluices to control the tides. In 1631 the Bedford River, a straight channel 21 miles long from Earith to Denver, was dug; it was completed twenty years later by a strongly embanked second channel. I may say that in the nineteenth century it attained peculiar fame, for here a great controversy as to the rotundity of the earth was settled by A. R. Wallace (see NATURE, April 6, p. 561).

Other projects were a "Middle Level" from Peterborough and a "Northern Cut"; the Earl of Lindsey was at work on the Lincoln fens. Everywhere there were disturbances as the whole economy of the region was upset, and "Mr. Cromwell" appeared at Huntingdon in 1638 as the chief opponent of King Charles, who was the "undertaker". Later Cromwell established himself at Ely, so that in the Civil War the Fens were not a harbour of refuge; of course all work ceased and there was much destruction. Internal peace encouraged a resumption of drainage in the southern Fenland, and Cromwell, now the statesman and great patriot, supplied both Scottish and Danish prisoners as labour; German prisoners were used similarly in 1917–18.

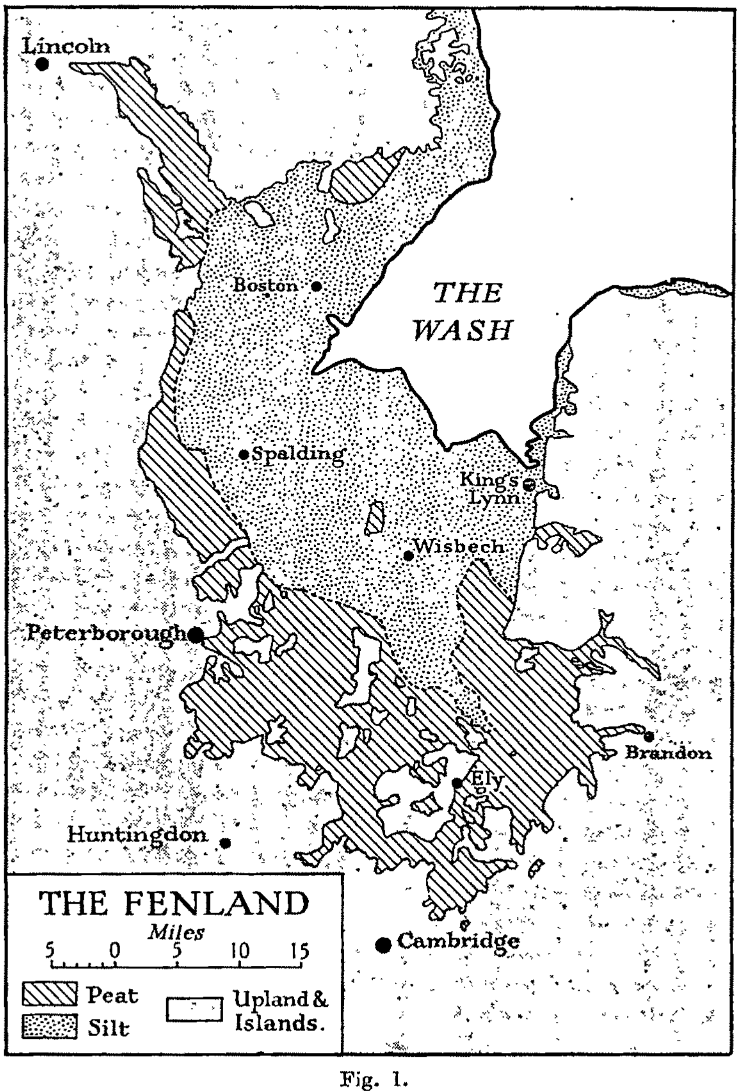

Fig. 1.
FROM "THE MEDIEVAL FENLAND".
THE PRESENT-DAY DISTRIBUTION OF THE LAND.

Innumerable difficulties were experienced in the eighteenth century due to the necessity of preserving channels for navigation, the inefficiency of the control of the outfalls to the sea, the looseness of the banks—this allowed a constant seepage—and, above all, the settling of the ground surface in the peat lands. The latter now lay considerably below the river-levels and the water channels that had been cut to carry the upland drainage into the rivers. Such shrinkage was experienced but slightly over the silt lands of Lincolnshire, so that the problems there were never so difficult as over the southern Fenland. For example, Wicken Sedge Fen is a catchment basin for the waters of its adjoining uplands, which are retained by means of the lodes and ditches surrounding it, while the surface of the peat lands of the neighbouring Burwell Fen now lies 7 ft. below, this difference representing the shrinkage*.

Nearer the centre of the Fenland in 1851 a column was inserted near Whittlesea Mere to the level of the peat surface. The mere was pumped by the new Appold system, and in three weeks 1,000 acres almost 3 ft. deep were drained; the column now stands 11 ft. above the surface of the ground, and there is 11 ft. of peat below. "The better the drainage, the greater the wastage of the peat surface", as Darby expresses it. A remedy was found ; the picturesque wooden windmills being built in the eighteenth century replaced ponies in raising the water from ditches in the lower Fenlands to the drainage lodes, which were straightened still more and strengthened ; the outfalls with the necessary sluices were likewise improved.

---

* "On the Level of the Fens around Wicken", by W. S. Farren, "Natural History of Wicken Fen", 190 *et seq* (1926). This is the part of the Fenland which best retains the conditions preceding the drainage. The vegetation is considered by Messrs. Godwin and Tansley, and the animal life by Dr. A. H. Evans and more than thirty other authors. These volumes have escaped Mr. Darby's bibliography.

Even at the end of the eighteenth century, conditions in respect to flooding were bad, as Young tells us, but the reclaimed land was the richest in England for corn and stock. Only a few years later the advent of the steam engine gave man the necessary power of control. An inscription on a pumping station of the New Bedford River reads :

These *Fens* have oft times been by *Water* drown'd,
Science a remedy in *Water* found.
The powers of *Steam* she said shall be employed
And the *Destroyer* by *Itself* destroyed.

Owing to railways, water traffic ceased to be important and coal became easily obtainable. The banks remained as the greatest danger, and, on occasions, even in the last decade every fenman near Ely has been called out to work both by night and day, while some houses were evacuated ; even troops and undergraduates from Cambridge were summoned to help in saving the banks, and hourly bulletins were issued. In these later days the control of the sea was better understood, but the problem here was vastly different from that of the Zuider Zee. The Fenland with its islands carried a considerable population, while the Wash, with its strong tides and open waters, makes the building of any large controlling dam, while quite unthinkable centuries ago, almost impossible even to-day.

Mr. Darby is to be congratulated on his remarkable study of the Fens. His every historical statement is supported by reference and selected with a real grasp of essentials. A chapter showing why the reclamation of the Fens became a national rather than a local matter would have helped in the study of his research. We should also like to know more of the Fenland peoples and their change from mainly pastoral to almost purely agricultural life. The principal crop in the eighteenth century was rape, its Fen name "cole". While at present it is only used for feeding purposes, particularly for sheep, its seed was then an extensive source of oil (rape, colza oil, etc.). The Fenland is no longer a grazier's country, but a land of corn, potatoes and beet. Occasionally mustard and buckwheat fields diversify the landscape, and in places horticulture, flower and fruit farmings have been extensively developed. As a whole, the Fens are prosperous, but many areas require scientific treatment, some perhaps a reclaying, others an attention to the water-level, and, surprisingly perhaps, others a retention of ground moisture that the addition of humus alone can give. Can we stimulate Mr. Darby to tell us, out of the abundance of his knowledge, a little of the more human side of the Fenlands, leaving aside for a time the technique of research ?

THE SETTLEMENTS OF THE PEAT WERE UPON THE ISLANDS (SEE FIG. 1). THE BRECKLAND COUNTRY TO THE EAST WAS VERY SCANTILY SETTLED.

OBITUARIES

Prof. W. C. Brøgger, For.Mem.R.S.

Dr. W. C. Brøgger, professor emeritus of mineralogy and geology of the University of Oslo, died on February 17, at the age of eighty-eight. Born at Oslo (Kristiania) in 1851, Brøgger started his scientific career as a zoologist, but soon, through the inspiring influence of Th. Kjerulf, professor of mineralogy and geology, entered upon the study of the two subjects in which he was to accomplish so much. Before he was thirty years old, he received a call to Stockholm as professor, having already to his credit a large number of important papers on mineralogy, general geology and palæontology. A particularly valuable publication of his early years is his treatise on "Die silurischen Etagen 2 und 3 im Kristianiagebeit, etc." (1882), where besides describing the stratigraphy and fossils of the Upper Cambrian and Lower Ordovician, he gave a preliminary, yet very comprehensive, survey of the igneous rocks of the district, a field of research which was to become the central one of his life. A most important geological paper from the Stockholm period is "Ueber die Bildungsgeschichte des Kristianiafjords", where the block-fault structure, with breccia and other accompanying phenomena, was demonstrated with exceptional clearness.

After the death of Kjerulf in 1890, Brøgger returned to Oslo as professor, and in the same year published what is probably his most famous paper, on the minerals of the syenite-pegmatite dykes of the Oslo area, especially of the Langesundsfjord in the southern part. This monograph of about 700 pages, coupled with his previous works, brought Brøgger the Murchison Medal of the Geological Society of London and other high rewards. It deals not only with a wonderfully rich variety of minerals, but also with wide petrological and geological problems, and has made the district classical, attracting to it great numbers of mineralogists and geologists from many countries, who often enjoyed the personal guidance in the field of Brøgger himself.

In the course of his long life, Brøgger continued to publish papers, especially on the alkaline rocks of the Oslo area, which furnished him with magnificent examples of rock differentiation and with material for the original description of very numerous and characteristic rock-types (lardalite, larvikite, nordmarkite, etc.). He showed the close chemical and mineralogical relation of the vast variety of rocks involved, occurring as plutonic bodies, as sills and dykes, and as lavas, with, in the main, a change from more basic to more acid types. Together with his assistant, and later on successor, J. Schetelig, he published a series of valuable geological maps of the Oslo area. Other of Brøgger's petrological studies dealt with Archæan rock-suites from southern Norway, and with a most interesting series of igneous carbonate-bearing rocks in the Fen district, just outside the Oslo area. The paper on the Fen rocks, reaching several hundred pages in length, was published in his seventieth year.

It is a most imposing proof of the universality of Brøgger as a man of science that we also owe to him the largest and, we may add, the most important work, that has been published on the Quaternary geology of Norway, a book (published in 1900–1) dealing with the unconsolidated deposits occurring around the Oslo Fjord, with far-reaching conclusions on the geographical and climatic history of the district; and further, that he has given us the first full treatment (1905) of the relation of the Stone Age settlements to the varying height of the shore line in the same district—an achievement of fundamental importance to Norwegian archæologists.

Brøgger has not only in his personal research work been one of the most prominent men of science whom Norway has ever produced (his scientific honours could be counted in scores, including, among others, membership of the Royal Society and the Paris Academy of Sciences), but in addition, through his administrative abilities, he was able to promote Norwegian scientific life in general more than any other man. Of particular importance was his successful work in establishing a great number of funds for scientific research, some of them very large, together with his activities on behalf of the University at Oslo, which resulted in a number of new appointments, new buildings (including the natural history museums), etc. Brøgger was also, as a matter of course, for decades the central and leading personality in the Academy of Sciences at Oslo, the activities of which owed much to him in different ways.

Brøgger was a man with wide interests outside the realm of science. It is perhaps worth mentioning just now that so long ago as 1899 he was one of a committee of six outstanding representatives of European intellectual life who in St. Petersburg requested an audience with the Czar of Russia, in order to lay before him an address, signed by more than a thousand prominent men, in protest against new and oppressive regulations towards Finland. They were not granted an audience, but their effort gained for them the lifelong gratitude of the Finnish people.

Olaf Holtedahl.

Prof. E. Mapother

Prof. Edward Mapother, who died on March 20 at the age of fifty-eight, had been medical superintendent of the Maudsley Hospital since its opening. Under his wise and energetic control, it became the chief post-graduate centre of psychiatry in Great Britain. Mapother was selected to fill the newly created chair of clinical psychiatry in the University of London, tenable at the Maudsley, in 1936. This was a personal appointment, which he continued to hold after he had resigned from his post as superintendent of the Hospital last December; it was an acknowledgment of the remarkably effective and far-sighted way in which he had used his position, from the beginning, to further psychiatric teaching and research.

Very great importance was attached by Mapother to this side of his work, and he felt strongly that it demanded the full time of one man, though it had been impossible for him to give it full time because of his administrative duties as superintendent, which were heavy. He fretted constantly at the restrictions which his other work imposed upon what he felt he ought to be doing in this regard, and more than a year ago he drew up a plan for the reorganization of the staff of the Hospital, which provided for the permanent separation, in different hands, of his two main functions. Owing to his tireless energy he accomplished much more, however, than he believed; and the influence of his teaching and of his guidance of the general lines of research was far-reaching.

Mapother was himself first and foremost a clinician; and all his investigations were primarily clinical, for example, into alcoholic morbidity, the mental effects of head injury, and the neuroses of war. He understood very well, though, that research must be conducted along many lines, somatic, psychological and social, if knowledge in this conspicuously difficult and complex subject was to be advanced, and he sought constantly to synthesize neuro-physiology and psychology. He recognized two important needs: to bring into psychiatry first-class men, and to ensure that they should have a good training both in clinical psychiatry and in whatever scientific methods they were going to apply to psychiatric problems. He was aware that, in the past, fewer able men have been attracted towards psychiatry than towards other fields in medicine, and he thought that the best way to remedy this was to build up an outstanding university centre the achievements of which, especially in research, would influence the standards and reputation of psychiatry. Through the help of the Commonwealth Fund of America, and especially of the Rockefeller Foundation, he was able to carry this project a long way; the London County Council showed a generous understanding of the value and importance of Mapother's efforts, which could not have been realized without its concurrence.

Mapother was a remarkably good judge of men, as was inevitable in so penetrating a clinical psychiatrist; he saw through empty professions and slipshod efforts, but was critically appreciative of good work. He therefore succeeded in gathering around him a group of able men who were glad to work under the conditions available at the Maudsley. He was determined that there should not be dilettante research in his hospital. He had seen the harm done by this, both in the more academic forms of research and in investigations into clinical problems, and he was careful, in the selection and training of his staff, to ensure that they should be thoroughly competent in the research methods employed. To his insistence on this must be largely attributed the high level of the research done under his stimulus and direction. He was happy to know, in the last few months of his life, that the War had not led to the disintegration of his staff, but that they were working, in the two hospitals to which they had removed, on those problems of psychiatry arising in war, to which he had himself paid so much attention.

Mr. E. T. Cottingham

Science, and more particularly the precision time measuring side, loses in the death of Mr. E. T. Cottingham one of the few outstanding men of Great Britain engaged in this research.

He was born at Ringstead, near Thrapston, and, although originally apprenticed to a tailor, his love for mechanical timepieces overcame his father's desires, eventually giving to Mr. Allen the task of teaching him to be a clockmaker in the village of Thrapston, where the whole of his life was spent.

Throughout, his interest has not been centred on one problem, for so varied were they that a few, such as church clocks, sewage pumping machinery, and fitting the surrounding blast furnaces with pyrometers, etc., occupied his attention. The proximity to Cambridge naturally gave him other problems which he so loved to solve. The advent of radio enrolled him as an early student and pupil and, I believe, he was one of the first to install his experimental set, dated October 1912. Wireless and time signals being inseparable, and from this to astronomical time-keeping, the care of the instruments at Greenwich in due course followed. He was also invited and accepted the invitation to accompany Sir Arthur Eddington in 1919 to Principe on the eclipse expedition. He will always be remembered for his simplification of the principles of Dr. Reifler's escapement, and the models he has left in the various observatories of the world stamp him as a genius in design and craftsmanship where simplicity is the keynote.

Frank Mercer.

We regret to announce the following deaths:

M. Nicholas Arnold, honorary general administrator of the Belgian Colonies, who had a large share in the development of the Congo under Belgian auspices, especially from a horticultural and botanical aspect.

Sir George Buchanan, K.C.I.E., consulting engineer especially concerning harbour, docks and river works, on April 14, aged seventy-four years.

The Right Hon. H. A. L. Fisher, O.M., F.R.S., warden of New College, Oxford, on April 18, aged seventy-five years.

Dr. A. C. Haddon, F.R.S., emeritus reader in ethnology in the University of Cambridge, on April 20, aged eighty-four years.

Prof. Heinrich Preiswerk, visiting professor of mineralogy in the University of Basle, aged sixty-four years.

Prof. W. R. Scott, F.B.A., Adam Smith professor of political economy in the University of Glasgow, on April 3, aged seventy-one years.

NEWS AND VIEWS

Prof. A. Virtanen: Helsinki

ON February 28, while the Russo-Finnish War was still in progress, the Editors wrote to Prof. Artturi Virtanen, of the Biochemical Institute, Helsinki, inviting him to send a message to scientific workers at large. Readers, and especially those interested in biochemistry as applied to agriculture, will be pleased to learn that Prof. Virtanen is safe and hopes to continue his scientific work. A letter, dated April 1, has just reached NATURE office, in which Prof. Virtanen writes: "I thank you for your kind letter of February 28, and am pleased to say that I have managed to retain my life during the war. My scientific work was, however, interrupted from the beginning of November. The danger to which my country and our civilization was subjected necessitated my taking up other kind of work. Our institute was emptied owing to the men joining the army and the young ladies being engaged on women's auxiliary labour. Three of my collaborators gave their lives for their country: L. Mansikkala, M.A., L. Eerola, M.A., and A. Arhimo, M.A., all men on whose forehead our Lord had written the word Honour. Together with Mr. Arhimo I have in this journal published two Letters to the Editors concerning the oxaloacetic acid and other keto acids in the plants. Following the destructive air bombing of Helsinki on November 30, I wrote my last letter to NATURE, as there was a possibility of my not being able to continue my work. Should circumstances permit, I hope to resume my reports to NATURE in the near future."

Prof. Alexander Findlay

FIVE years ago, Prof. Alexander Findlay published a characteristically comprehensive and interesting monograph on "The Teaching of Chemistry in the Universities of Aberdeen". His own approaching retirement from the chair of chemistry at Aberdeen, a chair which he has occupied with distinction for twenty-one years, inspires the thought that when some future scientific historian undertakes the task of bringing this volume up to date, he will find Prof. Findlay a subject as fascinating and as significant as any of his predecessors. A graduate himself of the University of Aberdeen and a research student under Ostwald at Leipzig, Findlay became recognized, very early in his career, as one of the leading promoters of physical chemistry in Great Britain and, before returning to his *alma mater*, held the positions of lecturer in physical chemistry in the University of Birmingham and professor of chemistry at the University College of Wales, Aberystwyth.

Pressure of teaching duties and lack of adequate laboratory facilities have unfortunately restricted Findlay's natural bent for original research, but ample compensation for this restriction is provided by the steady flow of text-books and 'popular' volumes of science with which he has instructed thousands of chemists and entranced multitudes of laymen. Few physical chemists of the present generation have not been nursed upon Findlay's "Phase Rule" or "Practical Physical Chemistry" (to mention only two out of many); no chemist of the present generation has attracted a larger outside following than Findlay in "Chemistry in the Service of Man" or "The Spirit of Chemistry". It is to be hoped that the greater degree of freedom afforded by the new phase of professor emeritus will permit him to delight the component body of his friends and admirers with many more such works of art.

Dr. H. Melville

DR. H. MELVILLE, of the Laboratory of Colloid Science, Cambridge, who has been appointed to succeed Prof. Findlay, is well known for his work on the mechanism of gaseous reactions. His first important series of papers dealt with the oxidation of phosphorus at low pressures, in which it was shown that the diffusion of active molecules or radicals to the walls of the reaction vessel is a dominant process in regulating the velocity of oxidation. Theoretical advance was also made by the discovery of a method for measuring the branching of reaction chains in the oxidation of phosphine, one of the essential processes in controlling explosions in gases. This was the first estimate of this coefficient. He has also contributed to our knowledge on the photodecomposition of the hydrides, the low quantum yield being traced and proved to be due to the occurrence of the recombination of the primary products of decomposition; this investigation led naturally to a supplementary one on the kinetics of exchange reactions of deuterium with the simple hydrides.

Latterly most of Dr. Melville's work has been directed to the elucidation of the mechanism of polymerization reactions. Suitable polymerizations have been found which occur in the gas phase photochemically and are amenable to kinetic study. One of the interesting results has been the discovery of molecules which grow, after photo-activation, in the dark for very long periods. Molecules of any size can thus be produced. By studying interpolymerizations it has become possible to build molecular sandwiches. Methods have also been developed for determining kinetically the molecular weight of polymers and for examining in detail the molecular statistics of the individual steps in a polymerization reaction, thereby leading to the exact control of molecular growth.

Karl Toldt (1840-1920)

PROF. KARL TOLDT, an eminent German anatomist and anthropologist, was born at Bruneck in the Tyrol on May 3, 1840. He received his medical

SHORT REVIEWS

ANTHROPOLOGY

Akiga's Story

The Tiv Tribe as seen by one of its Members. Translated and annotated by Dr. Rupert East. (Published for the International Institute of African Languages and Cultures.) Pp. xv+436+24 plates. (London: Oxford University Press, 1939.) 21*s.* net.

IF support were needed for the policy of the International Institute of African Languages and Cultures in encouraging the African to express himself in literary form, it might well be drawn from this volume. The author has been engaged for more than twenty years in collecting information relating to the traditional customs of his people, the Tiv, who, to the number of more than half a million, live on the banks of the Benué in northern Nigeria. Although it is true that his action long preceded any possibility of encouragement by the Institute, which came in only at the latest stage, the result of his labour, or at least that part of it which has now been published in translation, is remarkable for its power of logical thought, its arrangement, and its grasp of the essential. If the efforts of the Institute succeed in discovering writers of anything like the same calibre among the peoples of Africa, even if their numbers are relatively small, the policy is wise, and energies have not been expended in vain.

Akiga was the first of his people to attend a school, and although a Christian, and an active preacher of Christianity among his people, he records the traditional customs and beliefs of his people in pagan days with an objectivity and detachment which should find favour in the eyes of the anthropologist. Where his narrative falls short of the requirements of an ethnographical treatise, as it does at times, his translator, Dr. East, has done much to make good the deficiency by his supplementary and explanatory notes, in which he endeavours to supply the background necessary for understanding in a reader who knows neither the country nor the people. Author and commentator, between them, supply an instructive picture of a state of society which now to a great extent has passed away, largely owing to the efforts of the administration to restrict the leaning of the Tiv towards a preference for variety in their forms of marriage, by admitting one form only as legal. From Akiga's story it will be learnt why the election of one particular form, though well-intentioned, was mistaken, and why the native holds the white man as responsible for the ruin of the country.

Europe and West Africa

Some Problems and Adjustments. By Dr. C. K. Meek, W. M. Macmillan and E. R. J. Hussey. (University of London: Heath Clark Lectures, 1939, delivered at the London School of Hygiene and Tropical Medicine.) Pp. v+144. (London, New York and Toronto: Oxford University Press, 1940.) 10*s.* net.

IN this, the eighth of the series of Heath Clark Lectures of the University of London, "the educational, cultural and humanistic aspects of the History, Development and Progress of Preventive Medicine and Tropical Hygiene" have been construed in the broadest sense. They deal with the cultural changes and adjustments which are and have been taking place in West Africa as a result of the impact of European civilization. Dr. Meek opens the course with two lectures in which he draws upon his experience as an administrator, mainly acquired, as he points out, in Nigeria, to give in broad outline a summary of West African racial and cultural conditions and to indicate some of the principal social and economic factors affected by or affecting the course of contact development.

Prof. Macmillan, from his wide experience of African social and economic problems, provides an acute and penetrating analysis of a situation arising out of the development of the mining and cocoa industries and the difficulties which confront administration in the mixed communities resulting. Finally, Mr. Hussey considers the contribution of education to the solution of the problem of African development, construing his terms of reference in so wide a sense as to examine the position of 'indirect rule' as a factor in education. Those who are interested in the future of African peoples will find much stimulating food for thought in the indications afforded by both Prof. Macmillan and Mr. Hussey that indirect rule is not a magical formula which can be applied to all conditions and circumstances—as, for example, on the Gold Coast—without discrimination.

ASTRONOMY

A Star Atlas and Reference Handbook (Epoch 1920-1950)

For Students and Amateurs. By Arthur P. Norton. The Reference Handbook by J. Gall Inglis and A. P. Norton. Seventh edition. Pp. xii+52+18 maps+xiv–xxii. (London and Edinburgh: Gall and Inglis, 1940.) 12*s*. 6*d*. net.

IN the fifth edition of this work the constellation boundaries were drawn in accordance with the scheme adopted by the International Astronomical Union in 1930, and this plan has been followed in the sixth and present editions. Among the additions to the seventh edition may be noted a revised and enlarged index to contents and also on the last page an index to constellations and charts. Precession tables on p. xvii with an example of their use is another addition which will prove useful. The chief enlargement in the work has been made in a greatly extended list of "Interesting Objects", the number having been increased from 130 in previous editions to 523. The positions of these objects are referred to the equinox of 1950.0, which will be a standard of reference for a considerable time. The first four sections of the "Reference Handbook" at the beginning of the work supply useful information on a large number of astronomical terms, while the fifth and sixth sections give hints to observers and instructions on the use of the telescope. The work is intended primarily for the use of the amateur observer whose telescope is mounted either on an alt-azimuth stand or as an equatorial without graduated circles. It will certainly fulfil its object, and every amateur who is anxious to do useful work should be in possession of this volume. M. D.

An Easy Guide to the Constellations

(Based on the work of the same name by Rev. James Gall). With a Miniature Atlas of the Stars. By J. Gall Inglis. Pp. iv+86. (London and Edinburgh: Gall and Inglis, 1939.) 1*s*. 6*d*. net.

THE original of this book was published more than eighty years ago and was based on illustrated talks given to working lads in Edinburgh. The present author—a grandson of the original author—enlarged and partly rewrote the book many years ago, and now he has extended its scope to include some of the recent developments in astronomy.

A brief outline is given of many useful facts in astronomy in simple language that will prove very helpful to boy scouts especially, but others interested in the elements of astronomy will also find much useful information. The star maps are clearly drawn and with each of these there is a brief description of the times in various months when they south; this will help the amateur to identify them if in doubt. A very important feature is a list of constellations, stars and planets with the pronunciation of their names. The little work will serve a useful purpose. M. D.

BIOLOGY

Practical Animal Biology

By T. L. Green. Pp. x+276. (London: Allman and Son, Ltd., n.d.) 4*s*. 6*d*.

A PRACTICAL book in animal biology for use in schools, of a simpler nature than that used by first-year university students, is assured of a welcome. Mr. Green has combined a study of living animal types with investigation of their morphology. Shorter sections deal with chordate embryology, histology and physiology. There are nearly one hundred text figures. The text is fully descriptive and should be adequate for the scholar. Questions to be investigated by him are suggested throughout. The experiments in the physiology section have been well chosen and will certainly interest him.

The book, however, seems to have been hastily put together; there are inaccuracies in the text, and in some places where the text is sound the accompanying figure is at variance with it. For example, Fig. 55 tells the student that the abducent nerve supplies the *superior* rectus muscle, whereas the text and Fig. 56 indicate that this nerve goes to the *external* rectus muscle. As this nerve is usually very difficult to trace, what is the pupil to believe? Or again, the description of the innominate artery (p. 171) is correct; but any observant pupil will soon find out that the figure of it (74) is wrong. In the text the sequence of the factors of the right anterior vena cava in the rabbit (p. 170) should be *b*, *c*, *d*, *a*, *e*, *f*, and not as arranged by the author. In the embryology section, the germinal layers are named ectoderm, mesoderm and endoderm, but thereafter, without explanation, though with occasional lapses, they are called epiblast, mesoblast and hypoblast. Such inaccuracies detract from the value of an otherwise useful book, and illustrate how difficult it is to write a good text-book.

Laboratory Outline for General Zoology

By Prof. George Edwin Potter. Pp. 276. (London: Henry Kimpton, 1939.) 8*s*. 6*d*. net.

THIS sheaf of loose leaves, perforated for filing, comprises notes and hints on dissection, interleaved with sheets for drawings. The type method is employed, the range being somewhat similar to that of a first-year course in zoology in Great Britain, with the notable absence of a mammal. There are questions on each type, and suggestions for demonstrating various points. Outline drawings and schematic sections have been printed, and the student is expected to fill in the detail. How far this will encourage the student to scamp genuine observation is a debatable point, and most zoologists in Great Britain would consider it inadvisable to do too much for the student, however much time and labour for the teacher are saved thereby. The frog's skull, for example, has been drawn with every bone outlined, and all the student need do is insert the names and send in his sheet to be marked. The author aims at making the student "rely on his own judgment". Surely it is equally important to stimulate and train his powers of observation.

In the first insect type the name of the insect has been omitted, and the reviewer's copy has a duplicate page in this section. The descriptions are clearly expressed, and since scientific terms and new words are printed in italics, the student can look these up in the "Text-book of Zoology" previously published by the author.

Nature Parade

By Frank W. Lane. Pp. 316+53 plates. (London: Jarrolds, Ltd., 1939.) 15*s.* net.

BY far the majority of books which set out to describe events and happenings in nature are limited in that they are personal records of one or two observers only. The value of this book lies in the fact that the author has made a synthesis of innumerable records from various observers. The more general sections deal with subjects like animal food, toilet, sleep, leadership, strength, war and doctoring, while a considerable portion of the book is given over to a useful and original résumé of speed and locomotion in the animal kingdom. In a shorter section, which falls below the standard of the rest of the book, there is a rather verbose description of rare and mystical animals. "Nature Parade" rightly justifies its author's claim to be "a nature book with a difference" and contains much interesting information. It suffers by its too 'popular' and anthropomorphic approach and the absence of references to original documents. Some remarkable photographs by leading nature-photographers do much to enhance the usefulness of the book. T. H. H.

A Contribution to the Biology of North American Vespine Wasps

By Prof. Carl D. Duncan. (Stanford University Publications, University Series: Biological Sciences, Vol. 8, No. 1.) Pp. 272+54 plates. (Stanford University, Calif.: Stanford University Press; London: Oxford University Press, 1939.) 15*s.* net.

THIS memoir deals with North American paper-making wasps of the subfamily Vespinæ. It is divided into four sections: an introduction, a morphological section, a systematic section and a biological section. The morphology is concerned with the skeletal and muscular systems of *Vespula pennsylvanica*. The systematic part is concerned with genera and not species, while as regards biology numerous observations are given on habits, behaviour, nest-building and life-history. An extensive bibliography is appended, but the literature is not exhaustively reviewed, since the work is in no sense claimed to be a monograph.

CHEMISTRY

Laboratory Exercises in Inorganic Chemistry

By Prof. James F. Norris and Prof. Kenneth L. Mark. (International Chemical Series.) Second edition. Pp. xiii+574. (New York and London: McGraw-Hill Book Co., Inc., 1939.) 12*s.*

WITH the publication of a new edition of "Inorganic Chemistry for Colleges", Profs. Norris and Mark have now revised "Laboratory Exercises in Inorganic Chemistry" to make it complementary to the theoretical treatise. Additional experiments have been introduced to illustrate the chemistry of colloids, *p*H, and buffer solutions; otherwise the general plan of the book remains as before.

It is often said that experience is the best teacher, and the authors have fully supported this view in presenting a book which gives thorough training to students in all branches of practical inorganic chemistry. Very wisely, special emphasis is laid on the acquisition of fundamental bench technique as an early step in the student's training. This is followed by a systematic course covering the preparation and well-known reactions of many simple inorganic chemicals.

Each exercise consists of three parts: discussion, practical directions and questions. The last part is formulated in such a manner as to show that both the chemistry and the technique of the exercises have been mastered. An unusual feature of the book is the provision of blank pages for the students' notes. This system, which renders the book ultimately a combined text-book and note-book, should be of great value to the instructor.

The book can be heartily recommended to students entering on a chemical course. A careful study of the theory contained in the text and a mastery of the laboratory technique presented will prove a sound basis should the student desire to embark on more advanced chemical courses.

The Chemistry of Milk

By Dr. W. L. Davies. (Monographs on Applied Chemistry, Vol. 10.) Second edition. Pp. xiv+534. (London: Chapman and Hall, Ltd., 1939.) 25*s.* net.

IN reviewing the first edition of this book in NATURE, 138, 625 (1936), attention was directed to the rather large number of errors and inaccuracies in what should have been an indispensable and infallible weapon in the hands of the dairy technologist. So far as can be discovered, a few of these errors have been corrected in the new edition, but many remain. In addition to those cited in the NATURE review—and in others—may be mentioned a misquotation of Baumann and Steenbock (p. 490, last line but four), who found a 200 per cent variation in the vitamin A content of butter—not a 100 per cent variation, as stated by Dr. Davies.

The book remains the only work of its kind published in Great Britain. Every dairy chemist in the Empire probably possesses or has access to a copy. It is a national and imperial duty to secure that the facts supplied in this book are correctly given and clearly stated. The duty devolves upon publisher and editor, but still more on the author. It is therefore up to Dr. Davies, now himself the head of an important dairy research institute—a post that his own work in the field of analytical dairy chemistry fully justifies—to see that the third edition, which will surely be required in due course, is free from the many blemishes that disfigured the first and the second. A. L. B.

ENGINEERING

Electrical Engineering Experiments

Theory and Practice. By Prof. Henry R. Reed and Prof. George F. Corcoran. Pp. xii+500. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1939.) 22*s.* 6*d.* net.

THIS text-book will be very useful in electrical engineering laboratories. It covers a wide field, but most of the experiments have an individuality of their own and this gives a wide scope to the teacher, who will find much of the apparatus described and the instructions given in the book useful for physics and chemistry students. The large number of experiments described and the comparatively cheap nature of the apparatus required will be welcomed in colleges and technical schools which have only a limited equipment.

The text is divided into an introduction and seven sections. In the introduction the fundamental principles are first described, then direct current machines, alternating current circuits, transformers, synchronous machines, induction machines and electronics. Ample theory is given with each experiment, so that the reader can do most of them without detailed reference to other books. Exercises within the scope of a given experiment are so arranged that a portion or the whole can be performed, as time permits, without breaking up too much the continuity of the experiment. It will be particularly valuable to students taking a second year course in electrical, mechanical, chemical or telecommunication engineering.

The instructions given on how to write a report of the experiment done and the suggestions for further research work will save the teacher much trouble when the students ask him for hints as to suitable course work' to be marked for examination purposes. We can recommend the book to young graduates and others seeking for theses for higher degrees and to engineers who are beginning to forget the technique of laboratory research, and whose work makes it advisable that they should know it.

Instructions in Engineering Design

Vol. 2: Lattice Girder Bridge. By H. P. Philpot. Pp. viii+223+4 plates. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1939.) 10*s.* 6*d.*

IN the final stages of his study of engineering design, the student has the rather difficult task of working out a complete scheme for the construction of a machine or structure in accordance with a given specification. It is as if a soldier who had mastered the art of local tactics were required to prepare a strategic plan and the complete tactical operations involved in it. It is at this point that the text-books are found lacking, for they seldom show any one design worked out to its last and minutest details. These notes on the design of a lattice girder bridge have been prepared for the guidance of engineering students in response to many requests for a book to give them a lead in the methodical preparation of designs. The particular bridge dealt with has a span of 156 ft. between bearings and the girders are of the Pratt type. It carries a single line of rails and is of the 'through' type. The assumption is that it is being designed for the Indian railways and it is therefore necessary to follow the British Standard Specification for Girder Bridges, the Bridge Rules of the Government of India Railway Department and its Schedule of Dimensions, while the impact allowance conforms to the Indian loading.

Step by step the author works out the details and shows the application of the specifications quoted above, and it should be both instructive and satisfying for the student to see all the considerations involved being incorporated into a practical and efficient design. Beyond the mere calculations and results, the author's notes are of an explanatory nature, so that the progress of the design is made clear and the student is not placed in the difficulty of following quite obvious calculations without being able to see why this and not that method is employed. Not only is this a useful advanced class-book, it is also very suitable for the student or young draughtsman who has mastered the earlier stages of structural design.

MATHEMATICS

Applied Mathematics in Chemical Engineering

By Prof. Thomas K. Sherwood and Prof. Charles E. Reed. (Chemical Engineering Series.) Pp. xi+404. (New York and London: McGraw-Hill Book Co., Inc., 1939.) 24*s.*

FORMERLY, chemical science merely required, in general, a little elementary arithmetic and algebra, but to-day a vastly greater mathematical equipment is essential. The book under review, written by chemical engineers, gives a thorough survey of the actual type of mathematics now required.

The first of the nine chapters gives an introductory review of the mathematical processes to be developed. It shows that many of the generalizations constituting the basic laws of chemistry are, like those of physics, expressible in differential equations which depend upon much empirical information. Chapters ii and iii are devoted to the problems of constructing ordinary equations and of solving them. Chapter iv deals with partial differentiation with special reference to thermodynamics. Infinite series and their use in the solution of ordinary and partial equations form the subject-matter of the next two chapters. The authors' aim in treating Fourier's series and the Bessel functions as simply and practically as possible has been well fulfilled. Chapter vii is concerned with the methods of fitting data to empirical equations, numerical integration and differentiation and interpolation. Illustrations are given in Chapter viii of the many graphical methods in use in chemical engineering design, together with a short section on alignment charts. The final chapter wisely discusses the theory of errors and the precision of measurements. A few practical exercises are placed in an appendix at the end and a good index is provided.

The subject-matter is very clearly treated and, as stated in the preface, "it should be possible for anyone with a good grounding in the calculus to follow the text without difficulty". The authors also commendably point out that there is no quick and easy method of gaining proficiency in any branch of mathematics without sustained, serious and concentrated study. This is a very necessary warning to all practical students, and especially to those for whom this valuable book has been prepared.

Mathematics for Actuarial Students

By Harry Freeman. (Published for the Institute of Actuaries.) Part 1: Elementary Differential and Integral Calculus. Pp. viii+184. 9*s.* net. Part 2: Finite Differences, Probability and Elementary Statistics. Pp. xiii+340. 25*s.* net. (Cambridge: At the University Press, 1939.)

THESE two volumes are designed to replace the author's "Elementary Treatise on Actuarial Mathematics", published in 1931. The replacement is rendered necessary by changes in the mathematical requirements of the examinations controlled by the Institute of Actuaries. Part 1 contains the chapters on trigonometry and elementary calculus taken, with little change, from the earlier book. Part 2 is almost a new work, for the remaining text of the former treatise has not only been re-written and expanded to bring it up to date, but also new chapters on elementary statistics have been added. The first nine chapters, occupying 203 of the 330 pages of text, are devoted to finite differences, and the treatment of this somewhat difficult subject is both interesting and sound. The four remaining chapters are concerned with an elementary discussion of simple probability and statistics. Here, again, the author has developed the subjects with clarity and skill.

In both books, the text is well illustrated by worked-out examples, and each chapter concludes with a good set of exercises for the practice of the student. In addition, each part contains a number of miscellaneous problems placed at the end. Answers to all the examples are also given.

The books are excellently printed and should not only be useful to candidates for the Institute's examinations, but also of practical value to all students of the important branches of mathematics dealt with.

Higher Mathematics

With Applications to Science and Engineering. By Prof. Richard Stevens Burington and Charles Chapman Torrance. Pp. xiii+844. (New York and London: McGraw-Hill Book Co., Inc., 1939.) 30*s.*

WHILE special stress is laid, in the book under notice, on the practical application of mathematics to physics and engineering, yet the book compares favourably with a work on abstract rigorous analysis, although, as would be expected, the rigour is not carried so far as in a purely academic treatise. Of the nine chapters, the first four are concerned with the calculus of a real variable. These include the theorems of Rolle, Taylor, Green and Stokes; the Riemann theory of integration; ordinary and linear simultaneous differential equations with applications to electrical networks; numerical integration; brief discussions of Legendre and Bessel functions and series including the theorems of Féjer and Fourier. Chapter v is devoted to complex variables and elliptic functions, with applications to the pendulum and the rectification of an elliptic arc. Then follows in Chapter vi a consideration of determinants and matrices together with the elements of vector analysis, differential geometry and tensor analysis. Partial differential equations are dealt with in Chapter vii, whilst the last two chapters are devoted to the calculus of variations, analytical dynamics and an introduction to the theory of the real variable. The book concludes with a useful bibliography and a full index.

The text is, on the whole, clearly written, though obvious considerations of space have prevented a few topics from being as fully treated as might be wished. It is also well illustrated, both by carefully drawn figures and by fully worked-out practical problems, while numerous and judiciously chosen examples are provided for the student's practice. The authors have not only fulfilled their aim admirably but also have produced an interesting book, characterized by some excellent features, which should prove very useful to all students of applied science as well as to those of pure mathematics.

MEDICAL SCIENCES

Fundamental Principles of Bacteriology

With Laboratory Exercises. By Prof. A. J. Salle. Pp. xiii+679. (New York and London: McGraw-Hill Book Co. Inc., 1939.) 24*s.*

THIS book, as the author is careful to point out, is intended to serve as a ground-work for those who are beginning the study of bacteriology as a biological science; it is in no sense an advanced text-book on the subject. In nearly seven hundred pages of excellent print the elementary principles are covered, ranging from the physiology and morphology of micro-organisms to the bacteriology of water, soil, air, food, etc., with short chapters also on infection and immunity and the diseases of plants and animals. An attempt has also been made to make the work a combined text-book and laboratory manual. This has been done by including short experimental sections at certain points in each chapter. A useful bibliography of the more important text-books and original papers is included at suitable places throughout the text. The task of compiling a book of this nature is a formidable one for a single author, and no doubt, for this reason, some obvious defects have arisen. In certain sections the facts presented are either completely out of date or they are not, as yet, accepted by the majority of workers. On the whole, however, the material is well presented and should be readily assimilated by the student.

Dr. Salle's book may not readily find a place in the teaching departments of many of the universities in Great Britain, where bacteriology remains an *ad hoc* subject tacked on as required to larger branches of applied science. We have not, as yet, decided that as a separate branch of biological science it is a subject worthy of a secure position in the university curriculum. Nevertheless, the inclusion of this book in our libraries is to be recommended, if only to illustrate and direct attention to the advanced stage of the teaching of bacteriology, as a separate science, on the American Continent.

Tuberculosis and National Health

By Dr. H. Hyslop Thomson. Pp. xi + 260. (London: Methuen and Co., Ltd., 1939.) 10*s*. 6*d*. net.

THIS is a valuable contribution to the epidemiology of tuberculosis, by one who has had exceptional opportunities of becoming familiar with the disease in his capacity of medical officer of health and county tuberculosis officer for Hertfordshire, and of former tuberculosis officer or medical superintendent of sanatoria elsewhere. The subjects discussed include the incidence of tuberculosis in man and animals, the types of the disease, etiology and infection, housing and tuberculosis, relation of tuberculosis to milk supply, importance of early detection and treatment, modern treatment and after-care, and tuberculosis and the nursing service.

A bibliography of almost exclusively British and American writers, arranged according to each chapter, is appended.

Prevention of Venereal Disease

By Dr. Marie Carmichael Stopes. Third edition. Pp. xii + 62. (London: Putnam and Co., Ltd., 1939.) 2*s*. 6*d*. net.

THIS book is a revised and enlarged edition of a work published under another, though similar, title in 1921, and since reprinted on several occasions. It deals with the causes and prevention of venereal diseases and discusses the relation of promiscuous sex intercourse to their spread. The author, though not medically qualified, has written many popular works on sex subjects, and gives, in this volume, several quotations of the views of medical men on the questions at issue. She describes the technique of disinfection to be applied when risks have been taken, a procedure in which she is a strong believer.

Some of the medical references are not quite up to date, and the new treatment for gonorrhœa, which is one of the most important medical happenings in recent years, is not mentioned.

The psychological effect of statements about the uncertainty of cure has presumably been considered by the author; but those who have had experience of the phobias which the victims of these diseases are apt to develop would have preferred that vague assertions of this kind should not have been made.

Nevertheless, this book does a useful service in directing attention to diseases the causes and effects of which should be known to all young people, and concerning which there is still a denial of publicity through ordinary channels.

METALLURGY

The Physical Examination of Metals

By Bruce Chalmers. Vol. 1: Optical Methods. Pp. viii + 181 + 4 plates. (London: Edward Arnold and Co., 1939.) 14*s*. net.

METHODS which have not yet become part of the metallurgist's technique are the subject of this book. After a short introductory chapter on the properties of light, the applications of geometrical optics are discussed with special reference to the examination of metal surfaces, the measurement of reflectivity and the optical properties of thin films. Two chapters are then devoted to wave optics, under the headings of interference and diffraction phenomena. The principles of parallel and inclined plate interferometers are explained, and some applications, reaching a pinnacle of elegance in the author's precision extensometer, are described. Methods of examining films and coatings on metals involving interference colours and fringes are also described. Applications of diffraction phenomena include the measurement of fine meshes and particle size of powders, and an explanation of microscope resolving power.

Chapter v is devoted to the theory of polarized light, the experiments of Tronstad and of Lavery, and microscopical technique for identifying inclusions and determining state of strain. The final chapter deals with two optical methods in which the source of the light is the point of interest, namely, radiation pyrometry and spectrography. There is more 'meat' in this book than is revealed by a casual survey; the author has evidently taken great care in his selection of material, and, with his gift of clear expression, has enabled the average metallurgist to absorb quite a lot of physics without too much labour. Incidentally, one is still permitted to believe in an 'aether' for the purpose of the book.

Principles of Metallography

By Prof. Robert S. Williams and Prof. Victor O. Homerberg. (International Chemical Series.) Fourth edition. Pp. ix + 339. (New York and London: McGraw-Hill Book Co., Inc., 1939.) 23*s*.

THE popularity of this book is explained by the way in which the authors have succeeded in combining clarity with brevity. The treatment of fundamentals is, however, a little superficial in some respects. In the new chapter on plastic deformation, for example, no hint is given that metallic crystals are anything but perfect in structure, and one would prefer to see the early chapters, on the equilibrium diagram, extended at the expense of the final chapter on laboratory methods. The list of alloys given in the appendix might be replaced with advantage by a select bibliography. Printing, illustrations and binding are excellent.

MISCELLANY

Science and Civilization

By Dr. Bernard Lovell. (Discussion Books, No. 63.) Pp. 150. (London and Edinburgh: Thomas Nelson and Sons, Ltd., 1939.) 2*s*. net.

DR. LOVELL can be heartily congratulated on the admirable way he has discharged a difficult task. Within a hundred and fifty pages, he has given us a lucid and balanced outline of the training of the man of science, the organization of research, and its interactions with society, the factors which impede scientific advance and social progress, and a glimpse of the possibilities science holds for civilization could these obstacles be overcome; it should prove as stimulating to the general reader as to the scientific worker himself. This little book can be commended as a direct basis for discussion on the relations of science and society or as an introduction to the brief but growing scientific literature written with social consciousness. Its interpretation of scientific men and their work in the light of social responsibility, no less than its indication of the ways in which the frustration of scientific knowledge persists and indeed extends, and of the threats to intellectual liberty and life throughout the world, are well calculated to stimulate increasing numbers of scientific workers to consider the social aspects and responsibilities of their work, and attempt the interpretation of science in its social context.

The great value of the book is in its contribution to education for citizenship, whether of the scientific worker or of the general reader. It is therefore unfortunate that in his preface Dr. Lovell suggests that the universities should be re-directed to produce men educated as citizens *instead of* exact scholars. Great as may be the need for the universities to serve the community by providing graduates who are trained as citizens, competent to think accurately about the great problems of to-day and alive to the human issues underlying the decisions they are called upon to take, it must not, as Dr. Lovell's words seem to imply, be at the expense of either scholarship or the critical intelligence they are equally called upon to exercise. Changes in teaching or curriculum at the universities which will assist the development of personality and social consciousness are indeed desirable. They must not, however, be allowed to impair the integrity or exactitude of scholarship or scientific competence.

Civil Defence

A Practical Manual presenting with Working Drawings the Methods required for Adequate Protection against Aerial Attack. By Capt. C. W. Glover. Second edition, completely revised and enlarged. Pp. xviii+764+74 plates. (London: Chapman and Hall, Ltd., 1940.) 36*s*. net.

THE defence of the civil population against air attack has become a science of considerable magnitude, in which the problems cover a wide range from structural engineering, chemistry and fire fighting to the control and psychology of crowds. This second and enlarged edition of Capt. Glover's book is a very useful and comprehensive manual of protection against aeroplane bombs, in which technical details, graphs, mathematical data and costs are given. It also deals with matters of general interest. The diagrams of bombs, twice the size of a man, and the fact that in some of the raids in the War of 1914–18 one third of the casualties were caused by fragments from our own anti-aircraft fire, will come as a revelation to many people.

A large part of the book is devoted to shelter protection in buildings, trenches and dug-outs, and comparative costs are given. Alternative solutions to the pressing problem of the replacement of crumbling sandbag parapets by such methods as sand-filled hollow concrete blocks are not, however, mentioned, and the difficulty of the all-important question of the draining of trenches and dug-outs receives little attention.

There is a fascinating chapter on camouflage, one on anti-gas measures, with appendixes giving the properties and effect of the various war gases, and another on factory protection.

In the chapter on the organization of A.R.P., diagrams show the organizations in France, Germany and England. The complexity and lack of co-ordination in the English organization compared with the Continental nations is very marked, and lends credence to the story that at a certain first aid post and party depot, one half was sandbagged and the other not, since the Home Office, which deals with first aid parties, said 'sandbags' and the Ministry of Health, which deals with first aid posts, said 'no sandbags'. E. H. K.

Problèmes de la vision

Par Armand de Gramont. (Bibliothèque de Philosophie scientifique.) Pp. 282. (Paris: Ernest Flammarion, 1939.) 22 francs.

THE title of this book is somewhat misleading, since in its short compass it covers the essential facts of how we see, and adds many suggestions which are not to be found elsewhere. It consists of three parts: (1) the eye and its defects; (2) the spatial medium—points, lines, directions, optical delusions, surfaces, volumes, stereoscopic relief, and architecture; (3) chromatic transmission—heterochromatic photometry, colour sensations and contrast, colour blindness, and the perception and transmission of colours.

The author writes with the remarkable clarity and scientific accuracy which we associate with the best French men of science; but he is no slave to orthodoxy. Whilst the facts are accurate, the interpretation of function shows a bias towards the less generally accepted theories. Thus, owing to the acknowledged difficulties of the morphological discrimination of rods and cones, he is inclined to undervalue the physiological arguments in favour of the duplicity theory, which, indeed, receive less attention than they deserve. He rejects Helmholtz's theory of accommodation in favour of that of Tscherning, and also both the Young-Helmholtz and the Hering theories for one of piezo-electric resonance of his own.

These peculiarities do not detract from the value of the book, especially for those already *au fait* with the subject; and its value is further enhanced by interesting applications of the facts to art and architecture. Thus he points out that oddities of drawing, such as those of El Greco—and it has also been said of Sargent—cannot be attributed, as has been done, to astigmatism of the painter's eyes. On the other hand he goes so far as to state that Vermeer's "View of Delft" shows characteristics which prove that the artist was myopic. These and other suggestions of a similar nature add greatly to the fascination of the book, reminding one of Shelford Bidwell's "Curiosities of Light and Sight".

PHYSIOLOGY

Sex and Internal Secretions

A Survey of Recent Research. Editor: Edgar Allen. Pp. xxxvi+1346. (London: Baillière, Tindall and Cox, 1939.) 54*s*.

THIS well-known book is sponsored by the Committee for Research in Problems of Sex of the National Research Council of America. The first edition, published in 1932 to celebrate the completion of ten years work by the committee, soon established itself as a standard work of reference; the second edition is much larger than the first. It contains twenty-four chapters by different authors, most of whose names are known as the leading authorities in the fields with which they deal, and most of whom contributed to the first edition, though several new names have been added including that of an Englishman—W. H. Newton.

The field covered by this book is so wide that few people could properly appreciate all the different sections, which cover the genetic basis and embryonic development of sex, abnormalities of sex, the biology and chemistry of the testes and ovaries, the behaviour of spermatozoa, gonadotropic substances, the lactogenic hormone, the relation of vitamins to sex, and sex drive. There is a chapter on sex functions in man written from the clinical point of view, which deals not only with disorders of the sex organs, but also with the relation of sex to disorders in other parts of the body such as anæmia, hæmophilia and skin disease. There is a section on the biological assay of androgens and œstrogens which directs attention to the many sources of error in such assays, but which fails to emphasize the large chance errors associated with assays on small groups of animals, or to indicate the methods by which they can be reduced. The book will be invaluable to all serious students of the physiology of sex, but will not interest the dilettante.

Hearing and Equilibrium

By H. Macnaughton-Jones. Pp. viii+128+15 plates. (London: Baillière, Tindall and Cox, 1939.) 7*s*. 6*d*.

THE author has some original ideas on the working of the middle and inner ears, which he has illustrated by means of mechanical models. The book contains no account of recent work on the ear by other investigators, which is regrettable. It is difficult for the reader to solve for himself the problems which arise from an attempt to correlate the hypotheses put forward with the electrical effects which have been observed to occur when the ear is stimulated by sound.

PSYCHOLOGY AND PHILOSOPHY

The Nature of Creative Activity

Experimental and Comparative Studies of Visual and Non-Visual Sources of Drawing, Painting and Sculpture by means of the Artistic Products of Weak-Sighted and Blind Subjects and of the Art of Different Epochs and Cultures. By Viktor Löwenfeld. Translated from the German by O. A. Oeser. Pp. xvii+272. (London: Kegan Paul and Co., Ltd., 1939.) 21*s*. net.

THIS most interesting book is a study in the investigation of the creative activity of poor-sighted and blind subjects combined with a comparative study of the art of different cultures. The first section of the book is devoted to the study of children's drawings, the second to those of the weak-sighted, the third to a generalized study. There are more than a hundred pages of illustrations of children's drawings, together with a selection of drawings from weak-sighted individuals and various representations of historical types of art. The artistic creations of the blind and weak-sighted are largely based on the sense of touch and other senses.

Psycho-Analysis

By Dr. Edward Glover. Pp. viii+139. (London: John Bale Medical Publications, Ltd., 1939.) 12*s*. 6*d*. net.

THIS small book, which is dedicated to the memory of Sigmund Freud, attempts to give in one hundred and thirty-three pages the theory and practice of psycho-analysis. It can be said at once that the author has succeeded very well. The book is divided into two parts, the first dealing with theory, the second with the application of the theory to clinical practice. The author's statement that the psycho-analyst's interest lies in the early recognition and prevention of psychotic breakdown may be very praiseworthy, but we wonder how many cases of psychoses have been prevented by psycho-analysis and how many precipitated thereby. It is a good little book and worth reading.

PRINTED IN GREAT BRITAIN BY FISHER, KNIGHT AND CO., LTD., ST. ALBANS.

education in Vienna where he attended the Josephinum under Hering and Lange. He qualified in 1864, and twelve years later was appointed professor of anatomy at Prague where he superintended the construction of an anatomical institute, and after his transfer to a corresponding chair in Vienna collaborated with C. Lange in creating a similar institute there. In 1877 he published a text-book on histology, of which the third edition appeared in 1888, and in 1896–1900, in conjunction with Alois Dalla Rosa, brought out an anatomical atlas which went through fifteen editions, of which the third was translated into English by M. Eden Paul in 1919. His other anatomical works included contributions to the study of fatty tissue, the structure of the mesentery, the anatomy of the human thorax and the growth of bone. After his retirement he devoted himself to anthropology, his most important work on this subject being on the form of the occiput in the population of southern Germany. He died on November 13, 1920.

Science and the Future of Man

THE social contacts and obligations of science, which was a subject of frequent reference in the proceedings of the recent meeting of the American Association for the Advancement of Science at Columbus, Ohio, notably in the addresses by Dr. Wesley C. Mitchell, retiring president, and Dr. Julian S. Huxley (*see* NATURE, February 10, p. 207, and March 2, p. 330), furnished an important thread in the argument when Dr. Kirtley F. Mather discussed the prospects of human survival in his Sigma Xi lecture on "The Future of Man as an Inhabitant of the Earth". On geological, palæontological and biological grounds he is prepared to allow man a future of probably at least some thousands of years. Even if this present age is an interglacial and not a post-glacial, man's specific adaptability to extremes of climatic environment, he maintained, would enable him to survive. There is, however, he argued, one circumstance which militates against man's prolonged survival. This is the fact that in his conquest of the material world, which is the fundamental characteristic of his recent progress in civilization, man is using up his capital, such as oil, at a far higher rate than he is using his income, that is, the products of natural increase; and a further and even more alarming feature is that that capital expenditure is increasing progressively as the enjoyment of its amenities extends to the less sophisticated peoples. Hence, Dr. Mather concludes, exhaustion of capital in possibly seventy years or less may seriously curtail man's future.

Notwithstanding this depressing outlook, Dr. Mather does not despair of the future entirely in this respect, for he points out that science in its practical application has come to the rescue, and it may be anticipated will do so even more, by the provision of substitutes which will take the place of the capital material now being expended. He gives as an instance the substitutes for the oils, notwithstanding cost, and the same applies to other non-renewable resources. Another consequence of the activities of science in providing substitutes for these capital resources, of even greater topical interest at the moment, is that by liquidating international rivalries in pursuit of the policy of 'grabbing' the sources of supply, science will liquidate the basis of international jealousies and "may make it truly practical to beat our 'swords into ploughshares, our spears into pruning-hooks'." Finally, in regard to the organization of society, Dr. Mather pointed out that in the present rivalry of ideologies, the man of science as citizen must in the future give more thought to the social consequences of his work. He must determine the uses to which the tools he devises may be put, and ensure the wise use of knowledge and constructive application of energy. In a democracy this can be achieved only when the majority of its citizens have the scientific attitude towards social problems and act in accordance with that attitude of mind--a Herculean but not impossible task for education.

Norwegian Fauna

HOSTILITIES in Norway threaten some of the most interesting of European mammals, especially so the large deer, the numbers of which have already been reduced by excessive hunting, and which may be exterminated there as a result of food shortage, just as the European bison was exterminated from many of its European haunts in the War of 1914–18. In Norway, the European moose or elk (locally known as the elg or stordyr) has its strongholds in Sorlandet in the south-east, Ostlandet in the east and Trondelagen in the middle of the country. In some parts of the country it had received total protection by law and in other parts sportsmen were allowed to shoot only a limited number of bull moose during a short season at the end of September. In recent years more than a thousand moose have been shot in Norway in a year, compared with four or five hundred wild reindeer and two or three hundred red deer. There are also roe deer, lynxes and other mammals and a 20,000 acres national park existed for their protection at Sognligaård.

In recent years, Dr. Hj. Broch and the Nature Protection Society of Norway have done much to protect and increase such interesting birds as the osprey, kite, honey-buzzard and hen-harrier, whose nesting numbers were threatened. The 1932 Norwegian game laws protected all owls except the eagle and snowy owls, swans, pheasants, partridges, eider duck, woodcock, and gave a nesting season protection to most useful species. The smew nests in the north of the country, goosanders and mergasers on the waters, puffins, black guillemots and eiders about the rocky coasts, and there are also eagles, brent geese, herons, ravens, crossbills, bullfinches, shrikes, wrynecks, terns and divers. The Scandinavian peninsula has been shown to be the nesting haunt of many of the redwings, fieldfares, common gulls, starlings, wood-pigeons and woodcock visiting Britain in winter. The black woodpecker which nests here has been recorded in Britain on more than twenty occasions, including the last winter, and many ornithologists contend that these may be wild visitors.

Witchcraft in Swaziland

DURING the past week the Judicial Committee of the Privy Council has had before it the appeal of a Swazi subordinate chief, Fakisandhla Nkambule, against a judgment of the Swaziland court, by which he was convicted of having through a witch-doctor procured the death of one of his wives, his brother and his brother's wife. Among the grounds of appeal, it was submitted that the plea of guilty by the witch-doctor had been allowed to prejudice his case. The statements in the case throw an interesting, if somewhat lurid, light on the strength of Swazi belief in witchcraft, which the British administration has for long made strenuous efforts to suppress. It would appear that during the ceremony of placing the ghost rope over a grave to prevent the egress of the ghost, some twenty persons who were present, seated around a cauldron over a fire, partook of 'medicine' into which it is alleged commercial arsenic had been introduced. In the result, it was claimed, three of them had died.

Some hesitation was expressed by the appellant's counsel, Mr. Horace Douglas, in accepting the statement that in Swaziland a rope was believed to be an efficient barrier to a ghost's emergence from the grave; but he was reassured on finding the Greeks and Romans had used rope to keep evil spirits from their houses. Had the learned counsel referred to the works of Sir James Frazer, he would have found ample confirmation in many varied forms. In Swaziland itself the efficacy of the grass rope as a protection against the spirit of the departed is vouched for by the fact that for a certain period the widowed man or woman always wears a grass rope, the 'grave rope', around waist or neck, and this must on no account be removed until the ceremonial period has elapsed.

Austrian Academy in Great Britain

AMONG the thousands of refugees from Central Europe who have arrived in Great Britain during the past eight years or so have been many Austrians, debarred from their own country by their political opinions or by their race. Their numbers have included many eminent scholars, who have been allowed to make their homes in Britain; they feel now that they can discharge a part of the debt of gratitude they owe by contributing to the intellectual life of the country a fuller knowledge of the cultural achievements of Austria. To this end an Austrian Academy in Great Britain has been founded, the honorary president of which is Sir George Franckenstein, formerly Austrian Minister in Great Britain. The Academy is arranging lectures, which will be delivered, as a rule, in English, and will be open to the public, on Austrian culture, and it is hoped to organize exhibitions and other activities in collaboration with the Austrian Circle for Arts and Sciences.

The inaugural meeting of the Academy will be held at the Royal Institution on May 2; among the speakers will be Prof. Gilbert Murray, Prof. E. Schrödinger (for the Austrian Academy) and Sir William Bragg. A "Society of Friends of the Austrian Academy" has been established to collaborate with the Academy and to further its scientific and cultural activities. Members of the Society will be admitted free of charge to all regular lectures, and will have special privileges for other functions arranged by the Academy. The annual contribution is one guinea. Application for membership and subscriptions should be sent to the Hon. Vice-President of the Committee of the Austrian Academy in Great Britain, Baron Guido Fuchs, 15 Portman Square, London, W.1.

Industrial Health in War-time

THE Industrial Health Research Board of the Medical Research Council has published a short report on this subject (Emergency Report No. 1. H.M. Stationery Office. 6*d*. net). It is a summary of research findings, and it is claimed that by adoption of measures recommended, the efficiency, health and comfort of factory workers can be improved, production increased and discontent and fatigue avoided. Recommendations respecting work and fatigue suggest the avoidance of over-long hours and continuous work without intervals for rest, maintenance of Sunday rest and ordinary holidays, alleviation of boredom and elimination of unnecessary movements and effort. For efficient working, sufficient illumination and its proper control and distribution are necessary. Proper heating, the temperature varying with the kind of work, should be maintained, together with adequate ventilation and air movement, and a relative humidity not generally exceeding 70 per cent. A study of the causation of accidents is needed, from which may emerge means for their diminution and prevention. Lastly, recording and analysis of causes of sickness absence and accidents may contribute much information on loss of efficiency and well-being.

Chemistry of Foods

DURING the twelve years in which the Medical Research Council has supported Dr. McCance and his colleagues, the scope of their inquiries has been extended from determinations of the amount of carbohydrate in foods used in the treatment of diabetes to determinations of all the important organic and mineral constituents of foods, with the exception of the vitamins ("The Chemical Composition of Foods". By R. A. McCance and E. M. Widdowson. Med. Res. Council Special Report Series, No. 235. H.M. Stationery Office, 1940). Foods have been analysed, both raw and as prepared for the table, and studies have been made of the losses introduced by cooking.

The present volume includes previously published figures (Reports Nos. 135, 187 and 213), and contains all the quantitative data, in tabular form, likely to be required for work involving detailed knowledge of the chemical composition of British foods. Various facts receive comment. For example, 'Bovril' contained more potassium (3·59 per cent) than any other food examined, parmesan cheese more calcium (1·22 per cent), 'Marmite' more phosphorus (1·89 per cent), carrageen moss more magnesium (0·63 per cent) and sulphur (5·46 per cent), curry powder more iron (0·075 per cent), liver more copper (0·0058 per cent), and Gruyère cheese more nitrogen (5·9 per cent).

Vegetarianism in War-time

So closely is vegetarianism linked in many minds with food 'faddism' that one runs the risk of being regarded as eccentric if the consumption of more vegetables is strongly advocated. Nevertheless, the slogan 'Eat more Vegetables' is not only to form a central feature of the nutritional policy of the Ministry of Food during the War, but also, it is hoped, will be prominent in the post-War campaign to erradicate malnutrition from Great Britain. One simple fact stands out. Wholemeal cereals, vegetables, potatoes and milk or cheese provide all that is required for building a sound body and for maintaining good health. A little book of useful recipes, written primarily, one imagines, for vegetarians, entitled "Food in War-Time" (edited by W. H. White. London: G. Bell & Sons, Ltd., in conjunction with the London Vegetarian Society, 1940. 6*d.* net), should be widely read and used. It describes many dishes which would be valuable additions to our diet in ordinary times as well as in the special times for which it has been written.

Plastic Materials in the *Yankee Clipper*

A LARGE amount of plastic materials is used in the construction and furnishing of the American machines of the *Yankee Clipper* class, used in the trans-Atlantic air service. According to an article in the *Electrician* of March 8, colour plays an important part in the furnishing and decoration of these machines. The average American traveller is very critical of his travel-surroundings, and as he is relatively a prisoner in the machine for long hours on end, it is essential that his liking for cheerful surroundings be satisfied. Plastic decorations have been found to be most useful by the designers.

The dining-room has dome lights made of cellulose and giving a diffused light. The rear compartment, sometimes known as the 'bridal suite', is very luxurious, and is furnished with a dressing-table, etc. The lighting around the dressing-table has shades made of another type of cellulose acetate material. The dressing-table top is of synthetic resin laminated material. On the other hand, the wash-basins and table-tops in the ladies' dressing-room are in a blue vinyl material. The upper wall fabric is protected with sheets of transparent methyl material. Similarly, the cabin windows and the navigator's turret are 'glazed' with methacrylate. Plastic materials are also used for passenger signal flashing lights, for fuel tank gauges, and for some of the control knobs. The walls are made of opaque vitryl resin sheets, differing in colour in the various cabins and departments. Laminated material is used for some of the control pulleys, for spacers of various kinds and for certain bushings, and plastic materials form the basis of most of the paint and lacquer used on the machines.

The National Institute of Agricultural Botany

THE annual report of the National Institute of Agricultural Botany, Huntingdon Road, Cambridge, for the season 1938–39 has been issued. Much of the Institute's work concerns the trial of new varieties of crop plants, and the farmer who takes advantage of the frequent reports issued by the Institute can save himself a considerable amount of time, trouble and expense in trying things out for himself. Many of the notes supplied in the present report relate to types which are still only in the early stages of trial, but are none the less interesting because of that fact. At a time when high production per acre is a question of more than usual importance, the Institute's tests of the ability of certain varieties of wheat to respond to high levels of manuring without lodging will be followed with particular interest. The report indicates that seed of a carefully purified stock of Spratt-Archer barley and of a selected high-yielding strain of Rivet wheat have been recently made available to the seed trade.

Royal Geographical Society Awards

THE King has approved the award of the Royal Medals of the Royal Geographical Society as follows: Founder's Medal to Mr. and Mrs. Harold Ingrams, for their exploration, travel, and studies in the Hadhramaut; Patron's Medal to Lieutenant Alexander R. Glen, for his expeditions in Spitsbergen and North-East Land. The Council has made the following awards: Victoria Medal to Mr. O. G. S. Crawford, for his archæological maps prepared for the Ordnance Survey and his work on the Tabula Imperii Romani; Murchison Grant to Mr. Peter Mott, for his surveys in West Greenland; Back Grant to Mr. Gerald Seligman, for his glacier studies on the Jungfraujoch; Cuthbert Peek Grant to Mr. John Hanbury-Tracy, for his work in south-eastern Tibet with Mr. Kaulback and his journey in the north of South America; Gill Memorial to Mr. Alexander King, for his work in Jan Mayen in 1938.

Lectures on Food and its Use

A SERIES of lectures under the general title "The Nation's Larder" have been arranged at the Royal Institution with the approval and support of the Ministry of Food. The first was delivered on April 23 by Prof. J. C. Drummond, who spoke on food in relation to health in Great Britain during the past two hundred years. The remaining lectures of the series, which are being given on Tuesdays at 5.15, are on medical aspects of the use of foods (Sir Robert McCarrison), national food requirements (Sir John Orr), home production of food (Sir Frederick Keeble), manufacture, preservation and distribution of food (Dr. L. H. Lampitt), food and the housewife (Prof. V. H. Mottram) and the feeding of children (Dr. J. C. Spence). The lectures are to be published later in book form. Admission is by ticket obtainable, free of charge, from the Royal Institution, Albemarle Street, London, W.1.

Eighth American Scientific Congress

AN illustrated descriptive programme is now available of the Eighth American Scientific Congress, to be held in Washington, D.C., during May 10–18 (see NATURE, December 23, 1939, p. 1056). The Congress will be opened by President Roosevelt on May 10; and the first plenary session takes place on May 13.

Sectional meetings of the eleven sections occupy the remainder of the week, and the final plenary session will be on May 17. Government delegates of the other American Republics will be entertained by the United States Government at an official luncheon and at a banquet. The headquarters of the Congress will be at the Pan American Union, Washington.

Recent Earthquakes

ON April 13 there were further aftershocks of the Anatolian earthquake of December 26, 1939, in the region originally affected. The shocks were strong and felt as far away as Ankara. Great damage was caused to fifteen villages, six being completely destroyed. Sixteen persons were injured and four children are believed to have been buried beneath the wreckage. In the Caucasus, according to a report in *The Times*, the River Kars has overflowed, causing damage to the town of Kars. It is conceivable that with such extensive disasters as Turkey has recently suffered there may be some ground tilting even as far distant from the scene of the original disaster as the Caucasus.

On the night of April 17, a severe earthquake was experienced at Patras at the entrance to the Gulf of Corinth and to the north of the Island of Morea. No information is available as to the damage caused, if any, at the time of writing. The earthquake was felt in the Agrinion district, and more severely in the Missolonghi district, where in 1824 the poet Byron died fighting for Greek independence. It is well known that minor earthquakes are common in Greece, and destructive ones are by no means uncommon. It will be remembered that on April 22, 1928, at about 20h. 14m. G.M.T., a severe earthquake somewhat to the north of Corinth partly destroyed that city. More information is required before the epicentre of the present shock can be accurately determined.

The Night Sky in May

BY the middle of May, the night (sunset to sunrise, London) is of 8½ hours' duration. The moon is new on May 7 at 12h. and full on May 21 at 13h. Mars is in conjunction with the moon on May 10 and Venus on May 11. Jupiter and Saturn are now both morning stars but too close to the sun for observation. Venus is the brilliant evening star, setting less than one hour before midnight U.T. (that is, 1h. summer time). Its greatest brightness is reached about May 20, when its magnitude is $-4\cdot2$. Under favourable atmospheric conditions, it should be possible to see the planet in the daytime. Its time of meridian passage and altitude is given for May 5, 12, 19 and 26 —15h. 3m. (65·8°), 14h. 58m. (65·7°), 14h. 49m. (65·2°) and 14h. 35m. (64·5°). A telescopic view of Venus at this time will show the planet as a crescent, $\frac{1}{3}$ full in the middle of May and $\frac{1}{5}$ full at the end. Venus, with respect to size and mass, is almost the twin of the earth. A dense atmosphere evidently surrounds the planet and screens its surface from observation. Direct telescopic scrutiny shows almost a complete absence of markings, but ultra-violet photographs have recorded belts and bright spots which are probably high-level phenomena. Thus the rotation period of the planet remains in doubt, though probably one rotation takes nearly a month. Venus is the cynosure of the western evening sky, but as night comes on a glance may be spared for the stars Capella, Procyon, Castor and Pollux in the west; Regulus and Arcturus on the opposite side of the southern meridian; Spica low in the south, while Vega is above the north-eastern horizon. About May 4, members of the Eta Aquarid meteor shower (believed to be associated with Halley's Comet) may be seen in the early morning. On May 25, the 4th magnitude star, ρ Sagittarii, is occulted by the moon, the disappearance as seen from Greenwich taking place at 1h. 23·1m. at 90° from the north point of the moon's image; the reappearance being at 2h. 40·9m. at position angle 253°.

Announcements

DR. STANLEY B. BAGLEY has been elected president of the Society of Glass Technology in succession to Dr. C. J. Peddle.

IT is announced in *Science* that Prof. F. Joliot and Madame Irene Curie-Joliot, co-workers in the Radium Institute, Paris, have been awarded the 1940 Barnard Gold Medal for "meritorious service to science" bestowed by Columbia University every five years. The medal was established by the will of Frederick A. P. Barnard, president of Columbia during 1864–1889, and is awarded "to the person, if any, whether a citizen of the United States or any other country, who within the five years next preceding has made such discovery in physical or astronomical science, or such novel application of science to purposes beneficial to the human race, as in the judgment of the National Academy of Sciences of the United States is esteemed most worthy of such honor".

IN future the identification tag that every soldier in the German army must wear round his neck must indicate the blood group to which he belongs.

MIGRATION during 1939 increased the population of Australia by 12,537 persons, 1,636 of these being British. German nationals—almost all refugees—numbered 4,857. The gain to Australia of British migrants is the largest since 1929, when the depression stopped assistance to immigrants.

ACCORDING to *La Riforma Medica* of February 10, the annual birth-rate per 1,000 inhabitants in the chief capitals is as follows: Rome, 22; Buenos Aires, 18; Copenhagen, Budapest and Amsterdam, 15; New York, Berlin and London, 14; Warsaw, 13; Paris and Stockholm, 11; and Brussels, 10.

ERRATUM. NATURE, January 27, p. 148, letter entitled "First Benedicks Effect in Gas-free Mercury, as Influenced by tho Mean Temperature", for the formula $u = \mathrm{K} \,.\, \frac{3}{\Delta t}$ read $u = K \,.\, \overline{\Delta t}^{3}$.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.*

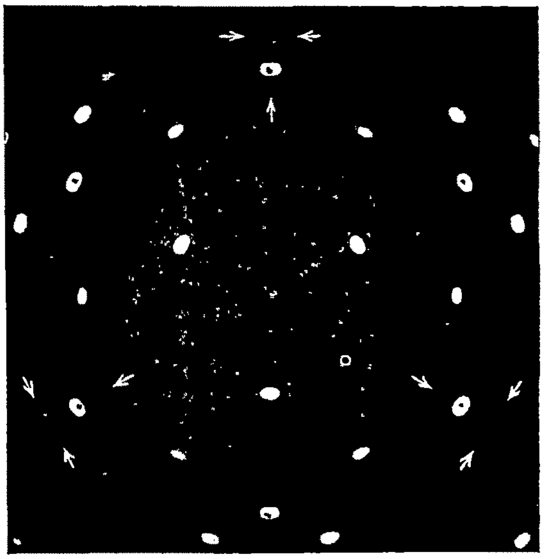
In the present circumstances, proofs of "letters" will not be submitted to correspondents outside Great Britain.

Notes on points in some of this week's letters appear on p. 673. Correspondents are invited to attach similar summaries to their communications.

Specular Reflection of X-Rays by High-Frequency Sound Waves

The principle that a regularly stratified medium selectively reflects a monochromatic beam of radiation incident on it at the appropriate angle is well known and forms the basis for the X-ray analysis of crystal structure. The spots appearing in a Laue diffraction pattern are, of course, due to such selective reflections of the incident X-rays by the periodic stratifications which represent the static structure of the crystal. A specular reflection of X-rays may, however, also result from stratifications of density which are not static but dynamic in character, and which may be considered as equivalent to stationary sound waves of very high frequency. We have observed and studied numerous examples of this special kind of X-ray reflection, but will content ourselves here with giving a single illustrative example chosen for its simplicity.

The accompanying reproduction represents the Laue pattern due to a crystal of diamond which has the form of a plate with faces parallel to an octahedral cleavage of the crystal, and through which passes a narrow pencil of X-rays from a tube with a copper anticathode and nickel filter. The pattern, as is to be expected, shows trigonal symmetry, the three spots marked with radial arrows in the figure being the reflections from the (111) planes, which are inclined to the trigonal axis at an angle of 19° 28′. Three other spots (indicated by tangential arrows) are also noticeable in the figure. The sharpness of these spots shows them to be specular reflections, but they are clearly not Laue spots, as is to be seen from the difference in their shape, as well as from the fact that there are no planes in the crystal which could give rise to reflections in the directions observed. These auxiliary spots must therefore be explained as arising from stratifications of density in the crystal which are of a dynamic nature.



Laue pattern of diamond along a trigonal axis (copper K_α radiation).

The origin of these spots becomes clear when we consider the effect on the structure of the diamond of its characteristic internal vibration. This is a periodic movement of the two interpenetrating lattices of carbon atoms with reference to each other in any arbitrary direction and with a very high frequency corresponding to 1332 cm.$^{-1}$ in spectroscopic units. If this vibration has a direction normal or nearly normal to an octahedral cleavage face of the diamond, stratifications of density are induced which vary periodically with time and have a spacing equal to that of the (111) planes in the crystal, but with an orientation variable within wide limits. These stratifications are therefore in a position to give a selective reflection of the monochromatic copper K_α radiation present in the incident pencil of X-rays. The observed position of the spots is in agreement with that calculated from the known spacing and wave-length. The explanation indicated is further confirmed by the fact that, using unfiltered radiations, we get two spots in each case, corresponding to the copper K_α and K_β radiations, and occupying distinct positions, as is to be expected.

We shall return in another communication to various other aspects of this new type of X-ray reflection.

Barometric Co-efficient of Extensive Cosmic Ray Showers

Counter experiments, intended to measure the rate of shower-producing radiation associated with extensive showers at sea-level, have given us an opportunity of measuring the barometric effect of showers up to 20 metres in mean diameter.

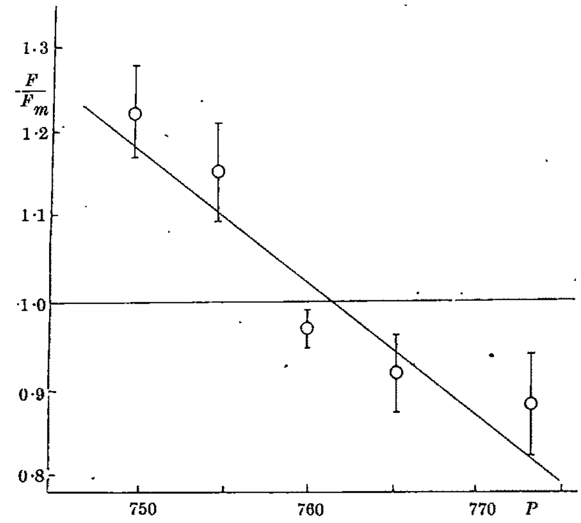

Fig. 1

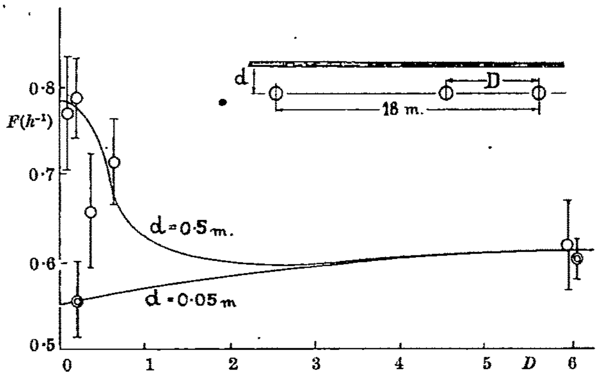

Fig. 2

We found that the barometric coefficient increases quickly with the diameter of the showers: for a barometric variation of 1 cm. of mercury, we found a corresponding variation of the frequency of showers of 4–5 per cent for 0·3 metre diameter showers: 8 ± 3 per cent for showers 12 metres in diameter, and 16 ± 3 per cent for showers 18 metres in diameter.

The measurements were made by means of a set of three counters, each of 120 cm.^{2} effective cross-section, under or above a thin tile roof.

Fig. 1 refers to a continuous run of four months, with daily recording. (D = 18 m.)

Comparison between measurements above and at different distances under the tile roof shows that, at sea-level, an important part of the soft rays associated with 20 m. showers are produced in the roof as ordinary secondary showers.

This is clearly shown in Fig. 2, which demonstrates the secondary coherence of most of the rays. No such increase was observed above the roof.

Thus, the distribution of rays in space follows closely the Poisson law above the roof and at several metres beneath; but the proximity of the roof introduces a secondary coherence between the rays. This explains the apparent discrepancy between the results of Auger[1] and those of Janossy and Lovell[2], for even a thin roof produces a large secondary coherence.

More experiments, now in progress in our laboratory, are needed before trying to reach quantitative conclusions.

Volume Integration of Dosage for X- and γ-Radiation

In radiation therapy as practised in this institution at the present time, the underlying principle adopted in the planning of treatment is to give a uniform tumour dose between 4000 r. and 6000 r. To achieve this, in deep-seated lesions, a multiple field technique has to be employed, and much radiation is absorbed which contributes not to the destruction of the tumour itself but to that of the normal tissues of the body. In the following note, methods are given for integration of dosage in a volume through which a beam passes.

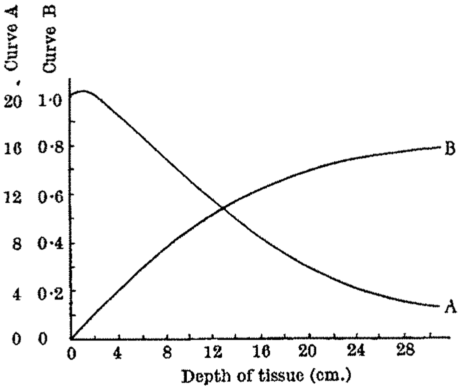
If at any point in a volume V, r is the dose of radiation in roentgens, then in that volume the integrated radiation dosage R is given by

$$R = \int_0^V r.dv, \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where R is measured in E.S.U. of charge.

To evaluate R. (*a*) In a series of complete isodose curves[1], the integrated radiation dosage can be evaluated graphically; the results of this method of calculation will be published in detail elsewhere. The few results already obtained are in agreement with the theory of section (*b*).

(*b*) In the case of radiation from a point source



Curve A : $\frac{r_x}{r_0} \cdot \frac{(40+x)^2}{40^2}$

Curve B : $\int_0^x \frac{r_x}{r_0} \cdot \frac{(40+x)^2}{40^2} . dx$

(for the purposes of the following discussion the X-ray beam considered is that from a 200-kv. Metropolitan-Vickers X-ray tube filtered through 1 mm. copper, 1 mm. aluminium at a focal skin distance of 40 cm.)[2], a simple method of computation of R has been evolved and the results are given below.

Curve A in the graph shows how the central ray of a large application (20 cm. × 15 cm.) is absorbed if its original area is 1 cm.^{2} at the surface of a 'water phantom'. The ordinates are the product of the depth dose[1] r and the geometric cross-section of the beam $\frac{(40+x)^2}{40^2}$ expressed as a fraction of the maximum incident skin dose r_0. in a solid angle of $1/40^2$. The final expression is $\frac{r_x}{r_0} \cdot \frac{(40+x)^2}{40^2}$, where x is the thickness of absorbing material. The area enclosed under the curve gives the ratio of the integrated dosage and the saturated skin dose per cm.^{2} of incident radiation, that is, $\int_0^x \frac{r_x}{r_0} \cdot \frac{(40+x)^2}{40^2} \cdot dx$. The integrated dosage for any depth of tissue can be calculated from curve B as the product

$$R = Ar_0 \int_0^x \frac{r_x}{r_0} \cdot \frac{(40+x)^2}{40^2} \cdot dx, \quad . \quad . \quad (2)$$

where A is the area of the applicator. This holds equally for all areas of irradiation and r_0 remains constant, being the maximum skin dose for a large applicator. For large fields, however, A represents the area of the spherical surface instead of its tangential plane, and if flat filters are used a correction is also required for oblique filtration at the edge of the beam.

From the graphs an approximate working formula for volume integration of dose may be obtained, for thickness of absorbing material x is greater than 5·6 cm. (exponential absorption only occurs after a depth of 5·6 cm.)

$$R = Ar_0 \times 5{\cdot}6 + \frac{Ar_0}{\mu}\left(1 - e^{-\mu(x-5\cdot6)}\right), \quad . \quad (3)$$

where μ is the absorption coefficient 0·085 cm.$^{-1}$.

This method can be applied also to point sources of γ-radiation, but in the case of radium beam therapy[3], where the source is not a point, the method of section (*a*) has to be applied. It is proposed to deal more fully with the problem of integrated dosage at a later date.

The Cyclol Hypothesis

Five sets of experiments have been reported in the past few years which have been claimed to bear on the cyclol hypothesis.

In a study of the infra-red spectrum of crystalline diketopiperazine, Kellner[1] found that the molecule is not in the enol form and is entirely or for the most part in the *lactam* rather than the *lactim* form. It is difficult to see the relevance of this result to the cyclol hypothesis, which has nothing to say as to the structure of such molecules.

It has been suggested that the study of the conditions under which CO–NH groups polymerize (dimerically to give double peptide bonds and trimerically to give triple peptide bonds) may prove to be a fruitful approach to protein synthesis[2]. The fact that α-piperidone is found to be monomeric in water and dimeric in benzene[3] does not conflict with this suggestion, which I desire to re-emphasize. Still less does it provide any evidence against the cyclol hypothesis, as has been claimed[4]. It seems in fact illegitimate to state, on the basis of these experiments, that "two experiments designed to test the cyclol hypothesis failed to support it"[5]. It has yet to be demonstrated in which respects, if any, diketopiperazine and α-piperidone can be regarded as models for the protein, or even as throwing any light on protein structure.

Analogous considerations apply to the unsuccessful attempt of Meyer and Hohenemser[6] to obtain *l*-leucyl, *l*-leucine and glycol glycine by mixing *l*-leucyl glycine and glycyl *l*-leucine. In this investigation no evidence was offered that a triazine intermediate was formed; the cyclol hypothesis does not require that dipeptides should form a triazine; had it been formed, the cyclol hypothesis does not require that it should break down into the dipeptides referred to. This experiment has in fact no relevance to the cyclol hypothesis.

The spectroscopic observations of native and digested serum by Haurowitz and Astrup[7] have also been cited as evidence against the cyclol hypothesis[4]. Here I need only direct attention to the work of Holliday, of which a preliminary account has recently been given[8]. It is necessary, in his opinion, before using such observations as arguments for or against the cyclol hypothesis, to distinguish change of absorption of the aromatic amino acids from the appearance of new absorbing centres.

A striking point of divergence between the classical and cyclol theories is the replacement of some or all of the skeletal CO and NH groups in the former by C(OH)–N groups in the latter[2,9]. In an attempt to settle whether or not the postulated cyclol OH groups occur in the native protein, Haurowitz[10] has studied experiments on the methylation and acetylation of proteins in which reagents such as acetic acid, acetyl chloride, acetic anhydride, dimethyl sulphate, diazomethane, ketene, etc., were used. His experiments, which repeat the results of the previous investigators, show that such OH groups, if present, are apparently not acetylated when the protein (egg albumin) is boiled (in the absence of a catalyst) with acetic anhydride, and are not methylated when the protein (egg albumin, horse hæmoglobin) is treated with dimethyl sulphate.

From these and the previous experiments, Haurowitz draws the conclusion that no cyclol OH groups exist in the native protein. But it is, in fact, very doubtful whether any conclusions regarding the presence or absence of these groups can be drawn from these negative findings. To do so it is necessary to assume that during these experiments the fine structure of the native protein remains intact, a very doubtful premise. Even if this assumption be made, it is further necessary to assume that the techniques used would certainly methylate or acetylate the cyclol OH groups, if they were present. In view of the fact that few $\geq$C–OH groups are at present known whose atomic environment bears any resemblance to that in the cyclol fabric, any such prediction seems dangerous. In point of fact, the nearest analogues to the cyclol $\geqq$C–OH groups seem to be those in the 1,3,5-trimethyl-2-phenyl (or alkyl)-2-hydroxy-4, 6-dioxohexahydrotriazines recently synthesized[11]. These compounds, it was found, are inert towards diazomethane and phenylisocyanate. These facts, *inter alia,* show that it cannot be dogmatically asserted that the cyclol OH groups, if present, would respond to the reagents listed above. In consequence, the negative findings under discussion go no way at all to proving the non-existence of the special type of skeletal OH groups postulated on the cyclol hypothesis.

Implicit in much of the criticism directed against the cyclol hypothesis is the curious argument that the fact that the cyclol structures contain features new to organic chemistry in itself constitutes evidence against the hypothesis[4]. This fact necessarily makes it difficult and probably impossible to test the hypothesis by such techniques as methylation and acetylation, even if difficulties relating to denaturation prove surmountable. However, since proteins have not yet been synthesized, and since they constitute a class of compounds which in many respects has unique qualities, the argument seems (if significant at all) to be in favour of the hypothesis. Failure to synthesize what have been called "simple substances with cyclol structure"[4] (a phrase which may prove to be a contradiction in terms) is also no evidence against the hypothesis. Criticisms of this type overlook the fact that all known proteins having molecular status contain thousands of atoms per molecule, and are by no means restricted in their constituents to one or two types of amino acids.

It appears then that the criticisms discussed above—in particular the five experiments—provide no evidence against the cyclol hypothesis. No statement of the case for the hypothesis is necessary, since an authoritative account[12] has already been given of the way in which it satisfactorily explains many of the well-known properties of the native proteins.

Demonstration of Thermal Diffusion in Liquids

CONSIDERABLE attention has recently been paid to a separation method for gases and liquids, which involves thermal diffusion and syphon action. In particular, the experiments of Clusius and Dickel[1] with carbon dioxide – hydrogen, and bromine – helium mixtures may be mentioned, while promising results in the separation of isotopes have also been reported[2]. Further, the same method gives good separations with aqueous solutions of inorganic salts[3] and mixtures of organic liquids[4].

Simple apparatus for illustrating these separations in the case of solutions has been constructed as follows. The solutions were enclosed by means of short rubber tubes within the vertical annular space between two concentric glass tubes. The diameter of the inner tube was 7 mm., its length 150 cm., and the annular space 0·5 mm. in thickness. Cold water was passed through the inner tube and steam through a surrounding jacket. With a solution of copper sulphate containing 330 gm. per litre, almost complete disappearance of the blue colour, indicating, therefore, a marked reduction in concentration, was observed at the top of the apparatus after eight hours treatment, while increase in concentration was sufficient to induce crystallization at the bottom of the tube.

A second apparatus, in which the annular space was only a few tenths of a millimetre in thickness, gave rapid separations with copper bromide and with cobalt chloride. The former is brown in concentrated and greenish blue in dilute solution, while the latter gives a blue colour in moderately concentrated hydrochloric acid which, on dilution, reverts to the characteristic pink. With initial solutions of intermediate tint, the anticipated colour changes clearly developed in the upper and lower sections of the tube in each case within two to three hours.

Sirius and the Constellation of the Bow

THERE is rather a remarkable coincidence (if it is a coincidence) in connexion with the ancient constellation figures to the south-east of Sirius, occurring in Babylonia, China and Egypt.

In the Chinese "Star Classic", reputedly of the third or fourth century B.C., but reassembled in the ninth century A.D., there is the phrase "The Bow and Arrow are nine stars to the south east of the Wolf" (the Wolf is Sirius)[1]. Schlegel shows in his diagram the arrow pointing towards Sirius, which might even be regarded as the tip of the arrow.

In Babylonia "in the late period Kaksidi [Sirius] was imagined as an arrow. Behind it stood the constellation Bow. Sirius is the shining point of the arrow; presumably one or more stars between this and the bow marked the shaft"[2].

On the Denderah round 'zodiac' from the small temple on the roof of the Great Temple of Denderah, now in the Louvre, there is a figure just to the left (east) of the Cow in the Barque (Sirius) which represents the goddess Satet bearing a bow and arrow[3].

Acetyl Content of Marinobufagin, Arenobufagin and Acetyl-marinobufagin

For marinobufagin, first isolated by Abel and Macht[1] from *Bufo marinus* and afterwards by Deulofeu and Mendive[2] from *B. paracnemis*, Slotta and Neisser[3] suggested the formula $C_{27}H_{38}O_6$, at variance with $C_{24}H_{32}O_5$ accepted by Jensen in many of his papers. They supposed that marinobufagin could contain one propionyl group.

The determination of the volatile acid content of several samples of marinobufagin by the Kuhn and Roth method[4] has given values lower than 1 per cent, so that acetyl or propionyl groups seem to be excluded from its constitution. Analysis of the samples gave carbon and hydrogen values according with Jensen's formula $C_{24}H_{32}O_5$.

When the same method was applied to acetyl marinobufagin[5], the acetyl content was found to be about 18 per cent, pointing to two acetyl groups in the molecule (calculated 17·76 per cent). Two easily esterifying alcoholic groups seem to be present (primary or secondary). On the basis of its elementary analysis, acetyl-marinobufagin has always been considered a mono-acetyl derivative. This difference will be further investigated.

From *B. arenarum*, Chen, Jensen and Chen[6] isolated a substance melting at 220° (correct.), to which formula $C_{25}H_{34}O_5$ was assigned. Jensen[7] states that the acetyl group is present, as by alkali hydrolysis acetic acid was detected as the silver salt.

We have isolated from the crude venom of *B. arenarum* another compound melting at 231–233° with a formula $C_{24}H_{32}O_6$ (elementary analysis) and without acetyl group (less than 1 per cent). Only further research on both compounds will explain the relationship between them.

That the method employed for the determination of acetyl groups is reliable results from the work of Wieland, Hesse and Hüttel[8] on bufotalinine, where correct acetyl values were obtained.

Substrate Specificity of Yeast Zymase

In a recent paper[1] further and seemingly conclusive proof was given that hydrolysis of maltose to glucose is not a necessary condition of maltose fermentation by living yeast cells. It may be noted that one of the findings upon which this conclusion was rested has now been independently confirmed[2]. Results since obtained suggest that not only is the mechanism of maltose fermentation *in vivo* different from, but also that it is not inclusive of, the glucose fermentation mechanism.

(1) It has been found that maltose fermentation by maltase-poor baker's yeast is strongly inhibited by the presence of methyl α-glucoside, but that under the same conditions glucose fermentation is unaffected.

The inhibiting action is not due to an inhibition of maltase since fermentation by maltase-rich brewery yeast and hydrolysis by maltase preparations of either baker's or brewery yeast are not subject to inhibition by methyl α-glucoside under the same conditions. It follows, therefore, that the mechanism of maltose fermentation includes a component which is not present in glucozymase and is not maltase.

(2) Conditions have been realized in which maltose ferments more rapidly than glucose. It is known that in aqueous or dilutely buffered medium, brewery yeast may ferment maltose and glucose at about the same rate. High salt concentrations depress the fermentation-rate of both sugars but have been found to do so more markedly in the case of glucose. The fermentation rate ratio of maltose to glucose in concentrated solutions of phosphate-citrate or other buffer salts may still be near 1·0 when fresh yeast is used, but far exceeds 1·0 when yeast which has been allowed to age is used.

The markedly superior fermentability of maltose in high buffer concentrations is proof that maltozymase is not merely maltase plus glucozymase. The same finding also offers support, though it does not itself constitute conclusive proof, for the view that maltozymase does not include glucozymase.

This conclusion is not opposed to any known fact of maltose fermentation, and finds further support in several observations which reveal primary differences in the fermentation mechanisms of maltose and glucose[3,4,5]. Also it should be mentioned that the *p*H-activity curve of maltose fermentation by baker's yeast is not given by glucose, and, as has been confirmed by us, is essentially different also from the *p*H-activity curve of either cell-bound or free yeast maltase[2,1].

The question may therefore be put whether the time-honoured term 'alcoholic fermentation of sugar' does not in fact cover processes which are different for different substrates.

It is intended to give a fuller discussion of this problem, details of the present experiments and a report of experiments on the alcoholic fermentations of sucrose, raffinose, and lactose in a later paper.

A Decalcification Fluid

Since my former communication[1], I have had opportunity to conduct a number of experiments with the sodium hexametaphosphate decalcifying fluid reported.

Using the formulæ given by Gray[2], I find that a 25 per cent solution of the sodium hexametaphosphate is miscible in all the basal fixing solutions mentioned, except those containing alcohol. I have not been able to test the platinum chloride ($PtCl_2$) solution. With alcoholic solutions, the sodium hexametaphosphate apparently forms an emulsion which separates out in a short time. This immiscibility with alcoholic solutions is no great drawback, since all of the usual fixatives containing alcohol also contain acetic acid. The object of the sodium hexametaphosphate is to avoid the 'gasing' caused by acid fixatives when used on calcareous material, and hence, as a rule, these would not be used. Chromic acid fixatives do not cause appreciable gasing, and can be used to advantage.

To those fixatives which in Gray's paper are prepared by the addition of a large volume of water to the basal fixing solutions, I recommend adding instead the same volume of 25 per cent sodium hexametaphosphate solution. In other cases, the solution can be added as an addition to the normal fixative. In all cases where the material is in reasonably small pieces, decalcification takes place in the normal period of fixation.

I find also that the sodium hexametaphosphate solution is miscible with the usual solutions used for washing after fixation.

Carcinogenic Colouring Matters

PROF. J. W. COOK's article on "Cancer-Producing Chemical Compounds" published in NATURE of March 2 raises questions of extreme importance for all those who employ artificial colouring matters in the manufacture of articles intended either for internal consumption or for application to the skin, or whose business it is—as in my own case—frequently to have to give advice about suitable colouring matters to use for either of these purposes.

May I suggest that it is highly desirable that a full report of the experiments mentioned by Prof. Cook should be published, and that the work should be continued ?

Prof. Cook's reference to a "limited range" of "permitted" food colouring matters in Great Britain is both puzzling, and, I venture to suggest, misleading. In Great Britain, unlike the United States of America, certain of the Dominions, and various other countries, there is no list of "permitted" food colouring matters. The use of certain metallic colouring matters, one colouring matter of vegetable origin (gamboge), and five specified coal-tar colours, is forbidden. These apart, food and beverage manufacturers are free to use any colouring matters they like so far as they are not injurious to public health.

A fairly considerable range of colouring matters is manufactured by firms specializing in the production of colours for the food industries. These include several azo-compounds, all of which are not sulphonated. Among the latter, special mention may be made of Yellow AB (benzene-azo-beta-naphthylamine), and Yellow OB (orthotoluene-azo-beta-naphthylamine). According to work reported by Prof. Cook, these two colouring matters should be regarded with suspicion ; but they are "permitted" colours in the United States, where legislation is far more stringent in the matter than in Great Britain.

There is a fairly general impression that toxicity of dye-stuffs is, at least in many cases, reduced or destroyed by sulphonation, which, at the same time, converts the substance from an oil-soluble dye into a water-soluble one. It is highly desirable to know, I suggest, whether this process also destroys any carcinogenic properties.

H. S. REDGROVE.

The Thatched Cottage,
Oxford Road,
Pangbourne, Berks.
March 18.

A FULL report of the experiments on the carcinogenic properties of 2 : 2′-azonaphthalene and its transformation products, and of the tests carried out on certain food colouring matters, to which reference was made in my recent article, is at present being prepared for publication. These experiments form part of an extensive series carried out by Prof. E. L. Kennaway and myself, with our collaborators, in the research laboratories of the Royal Cancer Hospital (Free), London.

I agree with Mr. Redgrove that my reference to "permitted" food colouring matters in Great Britain is a misrepresentation. Changes in my circumstances had deprived me of access to a correspondence which I had with the Government Chemist in 1936, when the tests with food colouring matters were begun. I have now been able to consult this correspondence and it is clear that the reference in my article to tests carried out with "a selection of these permitted dyes" should have read "a selection of the relatively few dyes in common use as food colouring matters".

The unsulphonated dyes mentioned by Mr. Redgrove undoubtedly require, and will receive, further attention. I was not aware that Yellow AB and Yellow OB are used in the food industries, and from inquiries which I have now made it would appear that these dye-stuffs are very little used in Great Britain.

High Proportions of Homostyle Plants in Populations of *Primula vulgaris*

As part of a study of heterostyly in Primula, with particular reference to the fertility relations existing between the two normally occurring types, pin and thrum, counts of their proportions in natural populations have been made. My own data have been supplemented by some counts made by friends and colleagues in various parts of Britain.

By far the most striking of the populations of *P. vulgaris* so far discovered are some from Somerset. I received from Miss M. Ll. Jones a collection of flowers, one taken from each plant selected at random in Sparkford Wood. Out of a total of 323, 102 were pins, 11 were thrums, and 210 were long homostyles, that is they had the anthers in the thrum position, while the style was long with the stigma in the pin position. A few stigmas were examined microscopically, and they all had long papillæ.

There are further counts from the same district made by Mr. P. B. Pitman, but in none of these have I examined the flowers. In an area of Sparkford Wood, slightly overlapping the first, the proportions found were 145 pin, 15 thrum, 468 long homostyles. It appears that the population within the wood is far from uniform, and is thus not likely to be even approximately in a state of stability. In another wood about five miles away, 152 pin, 103 thrum, 177 long homostyles were found. In contrast to these, a count on two banks near Maperton, in the same district, showed 46 pin, 75 thrum, 7 long homostyles, and 41, 40, 2 respectively.

Three styles from the Sparkford flowers were dissected and stained, and it was found that the pollen which was on the stigma had grown well. The grains were large, of the thrum type, and because of the shortage of thrum plants in the wood may be assumed to have come from a long homostyle flower. The fact that the stigma is usually more or less in contact with the opened anthers makes it reasonable to assume that self-pollination is the rule in homostyle plants. Further, experiments with a long homostyle *Primula veris* in 1939 showed that it was quite self-fertile.

It seems likely, therefore, that long homostyles in *P. vulgaris* are always self-fertilized. If such plants appear in a population, their fate depends upon the viability of the homostyle homozygote. If it is inviable, the gene combination responsible for homostyly would be eliminated from the population if thrums were present; if only pins and long homostyles occur, then at stability these will be present in the ratio $1 : \sqrt{2}$. If the homostyle homozygotes are viable, the ultimate population should consist entirely of them.

If, then, a long homostyle appears in a normal population, it should spread, provided the homozygote is viable; thrums should decrease more rapidly than pins, but both forms should ultimately disappear. The striking heterogeneity in the counts from different populations in the same area would seem to be due to different stages in the evolution of a new state of stability in each population following the appearance of long homostyles in that district. It is possible that further counts in the same district might reveal an orderly heterogeneity of the populations, with a centre of high homostyle concentration surrounded by populations with concentrations decreasing with distance from the centre. That is, one might expect that the gene combination responsible for homostyly would migrate outwards from its point of origin.

Further data must be obtained upon the occurrence of homostyles in natural populations. The facts communicated above show that in the counting of Primula populations it is important that all plants should be examined both for anther position and style length; long homostyles in which the stigma is not readily visible will resemble thrums until the corolla is removed.

J. L. CROSBY.

Botany School,
Cambridge.
April 17.

Points from Foregoing Letters

A LAUE pattern of diamond along a trigonal axis submitted by Sir C. V. Raman and P. Nilakantan shows additional sharply defined spots, which are believed to arise from dynamic stratifications of density in the crystal.

M. G. E. Cosyns finds that the barometric coefficient of extensive cosmic ray showers increases rapidly with the diameter. The particles of the extended shower produce numerous secondaries in even a thin roof, and these secondaries may account for anomalies in previous results on these showers.

A method has been devised by F. Happey for the calculation of integrated radiation dosage by considering the absorption of a saturated solid angle of beam of X-rays from a point source, and the results are expressed in a form which can be used clinically. A graphical method is also indicated for use with X- or γ-radiation.

D. Taylor and M. Ritchie describe some results obtained with a simple apparatus for demonstrating the Clusius-Dickel thermal diffusion effect in aqueous solutions. Striking colour changes in the upper and lower sections of solutions of copper sulphate, copper bromide and acidified cobalt chloride, jacketed in a long annular space between hot and cold surfaces, are very readily obtained.

For marinobufagin, the active principle from the venom of *B. arenarum*, the formula $C_{24}H_{32}O_5$ proposed by Jensen has been confirmed, but the acetyl derivative usually accepted as a mono-acetyl compound gave acetyl values that agree with a di-acetyl compound. From *B. arenarum* secretion a substance melting at 231–233°, and with formula $C_{24}H_{32}O_6$, has been isolated. It contains no acetyl, and it is different from the arenobufagin of Chen, Jensen and Chen.

It has been found by J. Leibowitz and S. Hestrin that by selective inhibition of the glucose fermentation rate through high salt concentrations, conditions could be realized in which brewery yeast fermented maltose far more rapidly than glucose. It is therefore concluded that maltozymase is not merely maltase plus glucozymase, and probably does not contain glucozymase.

Sodium hexametaphosphate, formerly reported by R. A. C. Wilks as a decalcifying agent, is miscible with all the usual fixatives, except those containing alcohol. Hence decalcification can take place at the same time as fixation, thus effecting a speeding up of these preliminary processes.

H. S. Redgrove stresses the importance of continuing the investigation on cancer-producing chemical compounds referred to by Prof. J. W. Cook in a recent article in NATURE, more especially in view of the use of azo dyes and derivatives of beta-naphthylamine for colouring foodstuffs and cosmetics. He points out that there is no list of 'permitted' colours for use in foodstuffs in force in Great Britain.

J. L. Crosby reports the occurrence in Somerset of populations of *Primula vulgaris* with very high proportions of long homostyles, and a considerable shortage of thrums as compared with pins. The effect of the appearance of such homostyles in populations consisting only of the normal forms is briefly discussed.

RESEARCH ITEMS

Measurement of the Nasion in the Living

Owing to the importance of determining the nasion in the living and the difficulties of so doing, special directions are given by the various authorities; these have been discussed and compared with his own elaboration of method by K. P. Chattopadhyay (*Amer. J. Phys. Anthrop.*, **25**, 2; 1939). Martin recommends light pressure with the lateral edge of the thumb up and down on the skin in the neighbourhood of the root of the nose, while Hrdlička, though also recommending the finger-nail or the point of a pencil, relies in the majority of cases on the experience of observation on skulls and dissecting room material. Lipiec and Oetteking worked on cadavera and skulls, and Ashley-Montague carried out experiments on "freshly-deceased human cadavera" with the purpose of their extension to the living, confirming his results by X-ray studies of ten living adult white males. But as the position of the superior palpebral sulcus, as used by Ashley-Montague as a point of departure of his horizontal tangential intersecting the mid-sagittal plane, has no constant relation to the nasion, a different approach has been tried. Ninety skulls of Bengal Hindus and twelve others in the University and Indian Museum were first studied, taking the distance between nasion and the intersection of the common tangent to the superior margin of the two orbits with the mid-sagittal plane. The mean value (all skulls) was found to be 5·311 mm. This method was adapted to conditions in the living whose nasal suture could be determined by palpation, by using caliper or tape and steel plate, with the tangent to the arched grooves when the eye is wide open as the line of reference. The result of the measurement of distance from nasion to the intersection of the tangent to the superior palpebral sulci with the median sagittal plane, with the eyes open, on one hundred Hindus is 5·39 mm.

Recent Advances in Insect Embryology

Mithan Lal Roonwal has contributed an extremely useful summary of the present state of knowledge of the embryology of insects (*J. Roy. Asiatic Soc. Bengal* (*Science*), **55**, 17–105; 1938—issued 1939). The process of gastrulation, the origin of the mid-gut epithelium and, specially, the problem as to the extent to which the orthodox germ-layer theory is applicable to insects, are among those aspects of the subject that are still under dispute. Recent embryological evidence points to the conclusion that the head is seven-segmental owing to the presence of two somites—the labral and pre-antennary in front of that bearing the antennæ. Some prominence is given to the author's own idea of multiphased gastrulation and its implications. Whether this conception will ultimately find general acceptance or not is too early to predict. The carbolic acid and water technique evolved by Slifer and King is commented upon as a definite advance on the practical side of embryology, since it has made the difficult and laborious process of sectioning yolky eggs a much simpler matter. The bibliography for nearly seven hundred references accounts for practically everything that has been written on insect embryology from the earliest papers up to and including many of those published in 1938 and later. There is also a classified list under which are grouped references to works on the embryology of separate orders, on experimental embryology, on bacterial symbiosis, etc. The author's name and the year of publication are given, thus enabling the reference to be traced in the alphabetical list.

A New Anaspid Fish

Erik A:son Stensiö deals with an interesting Ostracoderm of the order Anaspida ("A New Anaspid from the Upper Devonian of Scaumenac Bay in Canada, with remark on the other Anaspids", *Kungl. Svenska Vetenskapsakademiens Handlingar*, Tredje Serien, **18**, No. 1; 1939). *Endeiolepis Aneri* n.g., n.sp. although only two specimens are available, both imperfect, throws much new light on the Anaspids in general. The head, adjacent anterior part of the trunk and certain posterior parts of the caudal fin are lacking, but enough is preserved to show very definite structure. A survey is made of the Anaspids in general and the genus Euphanerops A. S. Woodward, of which only one specimen exists, is redescribed and shown to be well distinguished from the other genera. An important and striking feature in Endeiolepis is the remains of a paired row of long, freely projecting ventro-lateral scales developed from the gill-region and reaching to the anal opening. The anterior part of this row represents the pectoral spine apparatus and the ventro-lateral scales overlap each other and form together a paired, strong ridge, covered by a fold of skin, agreeing fundamentally with the ventro-lateral scales in the Cephalaspids. The author is of the opinion that Endeiolepis "had a real paired fin-fold strengthened with ventro-lateral scales, a paired fin-fold which according to its extent must comprise homologues both of a pectoral fin, respectively pectoral spine apparatus, and a ventral fin".

Algæ from the Iranian Gulf

During 1936–37 the Danish botanist, Mag. Køie, accompanied the Danish Fishery Investigation to the Iranian Gulf, and the algal collections have been named and collated by F. Børgesen (Danish Scientific Investigations in Iran. Part 1. 1939). A small collection in the Kew Herbarium from the Persian Gulf has also been examined. Previous to this, only about half a dozen algæ had been described from the Gulf, and the present gatherings also show that the flora is very poor and in strong contrast to the rich algal flora from Dwarka on the other side of the Arabian Sea. Børgesen ascribes this to the shallow depth of only 50 m., the high temperature of the water with a mean of 24° C. and the associated high salinity; the coastal waters are not removed by any ascending currents and also the general muddy or sandy type of bottom is unsuitable for algal growth. About 6 km. south of Bushire a coral reef showed a considerable algal growth with zones ranging from high on the littoral zone, *Cladophora nitellopsis* nov. spec. as the dominant type, through an *Enteromorpha compressa* zone, a broad belt of Colpomenia and then one with *Enteromorpha clathrata* with *Ulva Lactuca*; in all these zones a number of smaller red algæ were also present. Rocks farther out supplied Sargassum spp. and an Ectocarpus. On coral reefs on the island of Kharg, corals from 1–2 m. depth had numerous small algæ attached, but many of these were sterile and so poorly developed as to be impossible to determine. A rather richer vegetation was collected from the Bahrein Islands. The algæ of this gulf are probably mainly of interest as indicating the types which are able to survive under such unfavourable conditions.

Incompatibility in Antirrhinum

IT has been known since Lotsy's work in 1911 that the peloria flower of Antirrhinum sometimes segregated in a 1 : 1 ratio in place of 3 zygomorphic : 1 radial flowers in the selfed F_2 of a cross between these forms. If, however, the F_1 plants were intercrossed, a segregation of 3 zygomorphic : 1 radial could be obtained. Brieger has shown that peloria and the incompatibility factors $S_1 - S_F$ were closely linked and therefore the 1 : 1 segregation was accounted for. He claimed that a fertility factor in *A. majus* was not allelomorphic with the *S* factors. Marta Sharman (*Z. Ind. Abst. Vererb.*, 77, 3–17; 1939), however, shows that the usual allelomorphic series of S_1, $S_2 - S_F$, where S_F is a fertility factor, will account for all the data on the inheritance of fertility and radial flowers in species crosses in Antirrhinum, and therefore Antirrhinum may be brought into line with the general rule of inheritance of self-incompatibility on East's hypothesis.

A Beneficial Pathogen

AN interesting positive value of a parasitic fungus is revealed by S. H. Ou (*Sinensia*, 9, Nos. 5–6; September 1938). The plant *Zizania latifolia* is cultivated as an aquatic crop throughout China, the hypertrophied stem-tips serving as food. The fungus *Ustilago esculenta* is invariably present in the field crop. Characteristic swollen shoot tips are not produced, however, when the fungus is killed in the rhizomes by hot water treatment at 54° C. for 15 min. Zizania therefore owes its food value to the presence of a smut fungus.

Density of Seismograph Stations

A MOST interesting table concerning the above topic has been prepared by H. Landsberg for *Earthquake Notes* (11, No. 3; Jan. 1940). It appears that for the whole earth there are 478 seismograph stations with an approximate average of one per million square kilometres of surface. Europe has 159 stations with 14 per million square kilometres; Asia 156 with 3·7 per million square kilometres; America 110 with 2·7 per million square kilometres; Australia and New Zealand 22 with 2·6 per million square kilometres; and Africa 9 with 0·3 per million square kilometres. For individual countries, Japan has the most with 127, followed by the United States, 59, and Italy, 39. Several small countries only have one. Countries with the greatest number per million square kilometres are Japan, 322·0, Switzerland, 145·3, and Italy, 125·7. England and the Channel Islands (presumably Great Britain, Ireland and the Channel Islands) are reported as having 15 stations with a density of 99·3 per million square kilometres.

Raman Spectra of Co-ordination Compounds

AN examination of the Raman spectra of 4- and 6-co-ordinated compounds of platinum (2- and 4-valent) and rhodium (3-valent) salts has been made by J. P. Mathieu (*J. Chim. Phys.*, 36, 308; 1939), supplementing previous studies with tin, zinc, iron, cobalt, nickel, palladium and iridium salts. The Raman spectra of complex compounds of metals with the same co-ordination number and analogous electronic structures show similarities; the force constant *f* increases with the atomic number. A comparison of the cyanides or nitrites of elements of neighbouring atomic numbers but different co-ordination numbers (for example, Rh and Pd, and Ir and Pt) shows that *f* has very similar values for the two metals of each pair. This establishes a parallelism between *f* and the strength of co-ordinate linking as defined by Pauling, which remains constant in all octahedral complexes on one hand and in all square complexes on the other, whatever may be the outer electronic layer of the central atom ($3d$, $4d$ or $5d$), but increases on passing from the square complex to the octahedral complex. The paper contains a detailed examination of the modes of vibration in molecular models $[M(XY)_4]$, $[M(XY)_6]$ and $[M(XY_2)_4]$ in square or octahedral structures.

Absorption within the Stellar System

AMONGST the astronomical papers presented before the Columbus meeting of the American Association in December, was one by J. Stebbins, C. Hugger and A. Whitford on the colours of early-type stars near the poles of the galaxy. Evidence already exists for a thin absorbing layer of interstellar material near the galactic plane. The absorption is most conspicuous towards the line of the Milky Way, where it produces the great rift and various dark lanes in which the stars are partially blotted out. This general absorption is accompanied by the reddening of distant stars known to be intrinsically white from the character of their spectrum lines. Conversely, from the colours of these distant white stars, an estimate can be made of the amount of absorbing dust in space along the line of sight. The colours of about two hundred white stars near the galactic poles have been determined at the Washburn and the Mount Wilson Observatories. The results have been used to measure the absorption towards the galactic poles where we look through as little of the layer as possible; in other words, a measure is obtained of the optical thickness of the layer in the vicinity of the sun. From fifty of the stars with well-determined spectra, the measured space reddening corresponds to a total photographic absorption of 10 per cent at 300 light years from the galactic plane. The detection of absorption at greater distances will depend upon the accurate determination of the spectra of fainter stars. The present result agrees with previous measures of stars at greater distances along the galactic plane, where it is found that the absorption at three thousand light years is about one stellar magnitude; that is, the stars are reduced to about two fifths of their real brightness. Beyond three thousand and up to six thousand light years towards the anti-centre of the system, there is little further effect, indicating that the dark material thins out. Toward the centre of the galaxy, however, the absorption and space reddening are greater, and there is no evidence that we can penetrate to the end of the dark material in that direction.

EDUCATION IN WORLD CITIZENSHIP

THE League of Nations Union has recently established a Council for Education in World Citizenship which held its inaugural meeting at Oxford during April 11–15. The meeting, which took the form of a National Conference of Local Education Authorities and Teachers, dealt with "Problems of Education To-day in Relation to World Settlement after the War".

Some obviously uninformed views are abroad concerning the *raison d'être* and work of the newly formed Council and it may be appropriate to say here something of the reasons that have led to its formation.

The Education Committee of the League of Nations Union was formed some twenty years ago to instruct children in the aims and activities of the League of Nations. Throughout its existence it has had official approval and has enjoyed the support of many influential and important bodies within the Empire. Junior branches of the League of Nations Union have been formed in schools throughout the country with the approval and support of the local educational authorities concerned, and it would need an article in itself to outline the other activities of the Education Committee in sending children to Geneva, in providing summer schools and camps, in arranging courses of lectures, in making contacts with the youth of other nations, in a hundred and one ways endeavouring to break down those barriers of nationalist feeling which have, alas, culminated in the tragedy which overshadows our world of to-day.

All this good work went on with apparent success for some eighteen years, despite the deterioration in international affairs which succeeded what Dr. Gooch has called the "sunshine of Locarno". But of late years certain difficulties have become increasingly apparent. The League of Nations Union is, in its very essence, a policy-forming as well as an educational body. The Education Committee is, emphatically, not a policy-forming body—its functions are educational first, last and all the time.

Nevertheless, when the League of Nations Union found itself, on occasion, acting in opposition to the policy of the Government in office, this opposition was said (quite incorrectly) to be reflected in the policy of the Union's Education Committee, which was accused of dabbling in politics.

The issue was brought to a head by the Munich crisis of 1938, when many junior branches seceded, giving as their main reason that they wished to study international affairs without necessarily subscribing to the tenets of the League of Nations Union.

It seemed therefore desirable to form a council which, while being in general sympathy with the ideals which inspire and guide the work of the League of Nations Union, should have complete autonomy in the management of its affairs.

Hence the appearance of the new Council. Its objects are to foster mutual understanding and habits of co-operation between the peoples of the different countries and to take steps to ensure that students are trained in the principles of international co-operation, including the aims and activities of the League of Nations, and the terms of its Covenant. To these ends the council will encourage and assist such teaching of school subjects as will lead to an understanding of world affairs, the growth of civilization, the chief characteristics of nations and of national governments, the factors that unite and the differences that divide nations and the responsibilities of citizenship ; will assist both students and teachers in studying the causes of war and the means whereby a more just and stable world order may be created ; will seek to provide opportunities for pupils to appreciate the best in other peoples, and to make friendly contacts with boys and girls of other nations ; will seek to ensure that nothing in our colleges and schools shall arouse hatred and contempt of other peoples ; and will teach the principles of freedom and justice, co-operation and good faith as the foundations of the good society in the home, school, State and world community.

Here, surely, is a programme with which every lover of freedom and justice will find himself wholeheartedly in agreement.

The proposed membership of the Council is wide enough to absolve it from any charge of sectarianism. It includes representatives from practically every important educational body, most of the administrative bodies connected with education, adult educational associations, committees of the British Broadcasting Corporation, the British Film Institute and representatives of the Guides and Scouts movements.

The inaugural meeting's success was qualified by only one untoward happening. Prof. Susan Stebbing was forced to cancel, by reason of illness, her paper on "Training in Clear Thinking on Public Affairs". Otherwise, the meeting's success far exceeded the anticipations of the organizers. Syllabuses are notoriously dull, but the scope of the meeting is best indicated by a résumé of the titles of the addresses heard by the three hundred delegates who attended the conference. The opening address, on "World Citizenship ; the Growth of an Idea", was delivered on Thursday evening by the chairman of the Council, Prof. Gilbert Murray. On Friday a discussion on "The League of Nations ; what next ?" was opened by Mr. Noel-Baker. On Friday afternoon Mr. H. G. Wells and Prof. Allan Ferguson opened a discussion on "The Teaching of World Unity ; what is being done and what might be done in the schools". In the evening, Prof. C. E. M. Joad delivered an address on "Proposals for Federal Union". On Saturday morning, Señor de Madariaga, M. Jan Masaryk, M. Maheu (chief representative in Great Britain of the French Ministry of Information), Count Jean Balinski Jundzill (Deputy Director of the Polish Research Centre, London), Dr. Rudolf Olden (formerly assistant editor of the *Berliner Tageblatt*), Mr. A. C. F. Beales, Mr. Ivor Montagu and Mr. W. Arnold Forster took part in a round-table discussion on "Some Guiding Principle for the next Peace Settlement". On Saturday evening Miss Dymond (Principal of the Portsmouth Municipal Training College) presented a report on "The effects of the War on the Minds of Children". On Sunday afternoon, Miss Charlesworth presided over a conference on "The Work of the Council", and on Sunday evening the delegates were addressed by the Headmaster of Rugby (Mr. P. H. B. Lyon), who took as his subject "The Spiritual Foundations of World Citizenship". The final session of the Council, to sum up the work of the Conference, was held on Monday morning, and the concluding address was given by Mr. Kenneth Lindsay, Parliamentary Secretary to the Board of Education.

Throughout the meeting the addresses and discussions attained and preserved a high level of interest. The opening address by Prof. Gilbert Murray, with its insistence on the futility of any form of political or economic co-operation which is not backed by a real will to brotherhood—by an intellectual co-operation having a firm ethical basis—marked a line of thought which dominated the subsequent proceedings of the conference and which emphasized at once the difficulties and hopes attending any advance towards world unity.

So, too, the Headmaster of Rugby in his Sunday evening address. Therein he deplored the tendency of modern teaching to over-emphasize the ethical, and to lay too little stress on the religious outlook. In internationalism shorn of the religious habit of mind there was little driving force, and "as sentiments grew wider they grew shallower". He urged that religious education should be regarded as a fundamental necessity.

Mr. Noel Baker's address was an eloquent plea for a strengthening of the terms of the Covenant of the League. The League had not failed, in any true sense of the word. It had many successes to its credit, and, where its machinery had apparently broken down, the reason was to be found in the fact that commitments had been undertaken, had not been repudiated, but had remained unfulfilled. The address provoked a lively discussion.

In the afternoon's session on the teaching of world unity, Mr. H. G. Wells was as stimulating and provocative as ever. The present state of affairs in the teaching world (in particular the meagreness of the resources which the teacher had at hand in the matter of encyclopædias, books and apparatus) came in for some vigorous criticism. World unity was a fact; war was civil war; the non-combatant had disappeared, and the neutral was fast disappearing; League and Federal notions might well lead to failure, in the latter case because federated *blocs* might result, leading to war on a larger scale. It should not, however, be impossible to bring into one world opposition the oppositions which existed in the governments of all civilized countries, and so to persuade sovereign States to relinquish the control of matters which otherwise they would not relinquish. From the point of view of the teacher, old-fashioned history should be replaced by the study of the science of human ecology, the relation of man to his external surroundings—children should be taught, not by telling them little stories of kings and queens, but by showing them their relation to the world as a whole.

Prof. Ferguson pointed out that science teaching provided an ideal medium for fostering the international outlook, and for exhibiting some of the most important relations of the individual to the community of which he formed a part. They had heard much of the effect of the aeroplane and of other inventions and discoveries in annihilating distance, but there were other and hitherto rather neglected topics about which equally fascinating stories could be told. He instanced some of the details concerning the transport and storage of food, and the new and rapidly growing industry of plastics. As regarded the teaching of history, a little investigation had shown that many teachers in training colleges and in public and secondary schools were fully alive to the necessity for teaching the subject from the point of view of world history, and that experiments in the improvement of international understanding by way of camps, tours abroad, junior branches of the L.N.U., and exchanges of visits and of letters were by no means unknown. In the primary schools, too, the teaching of history had changed remarkably in recent years. Any widening of outlook must be based on accurate knowledge oriented by an emotional appeal.

Undoubtedly, high though its general level had been, the culminating point of the Conference was reached in Saturday morning's round table discussion, and the varied views and high qualities of statesmanship shown therein made a deep impression on the delegates. The prevailing impression left on the minds of many hearers was that, although some approaches to world unity may, on paper, seem preferable to others, yet, granted good will, almost any scheme would work; that the gravest task which faces the statesmen burdened with the responsibility of realizing any future proposals for peace is that of ensuring that the proposals shall be carried out in a spirit of mutual helpfulness; that hatred shall be reserved for the sin, rather than for the sinner; and, to that end, that the peace proposals shall be worked out in detail after an armistice period which might extend over a period of some years. The Polish speaker, in the course of a moving speech, suggested that in addition to the closer union of Britain and France which might be regarded as initiating a new world order, a similar union might be contemplated between Poland and Czechoslovakia.

Mr. Arnold Forster, who summed up the discussion, was not in favour of a long armistice, and suggested that four stages should be contemplated in the making of peace—a period of conversation, an armistice, a period for the drafting of the peace treaty, and, finally, a world conference at which the terms of a general settlement should be discussed.

Saturday evening's meeting, to which Miss Dymond presented a report on "The Effects of the War on the Minds of Children", evoked very general interest. The number of pupils who were the subject of experiment was 317, and all were in the 12-year age-group. Pupils were asked to write (without preparation) a half-hour essay on 'Why we are at war with Germany'. There was a majority (62 per cent of the boys and 60 per cent of the girls) who stated clearly that the war was due to German aggression.

Asked, "Who is your favourite hero ?", the members of the group showed surprisingly little interest in the outstanding figures of the day. Mr. Chamberlain scored four votes, Mr. Churchill three. Most of the boys voted for Nelson and Drake.

There were few reactions to war-professions in the answers to the question, "What would you like to be when you grow up ?—none at all among the girls, unless a desire to take up nursing be correlated with the War.

Perhaps the most interesting and illuminating answers were those given to the question, "What was the most important day of your life ?" Some

11 per cent of the boys and 12 per cent of the girls who had been evacuated mentioned the day of evacuation or that of the outbreak of war. On the other hand, a very large number voted for the day on which they sat for the junior scholarship examination.

Asked to continue a story which began, "There was a loud bang, Pat's heart beat fast," the boys tended towards adventure stories not necessarily connected with the War, girls to air-raid stories.

To the question, "In what period of history would you have preferred to live ?", the majority answered "The present time", and the surprising reason given was, "Because it's more comfortable." A significant number of girls chose a period in which they could wear a picturesque dress.

A free-association test, in which the significant words were "bang, ship, enemy aeroplane, shell", showed a strong war connexion with 'enemy' and 'bang', and it is interesting to note that 'shell' often evoked associations with the sea-shore.

Generally, the investigation showed that the War has had a considerable but not an overwhelming effect on the minds of children.

The impression which the conference as a whole has left on the mind of the writer of this review of its work is that the future of any successful approach to world unity lies in the hands of the teachers, and primarily in the hands of those responsible for the training of our youth below the age of fourteen; that we must rid ourselves of the delusion that there is a ladder of education with the primary school on the lowest rung, and the university on the topmost, and must realize that by far the most important years of education are those passed in our primary and senior schools, and that what happens in later stages is a divergence, rather than a climb; that there is an urgent need for the raising of the status and for the broadening of the training of those destined to become teachers in elementary schools; that the education of such teachers should not be regarded as ending with their period of training, but that every encouragement should be given to their making contacts with the world of thought which lies outside their school; that it is a desirable thing to teach school subjects from a point of view wider than that of mere nationalism, but that such knowledge must be exact, and must, moreover, be informed by spiritual forces supplied, indirectly, in the home as well as in the school; forces, too, which the teacher must experience in his own home and college ere he can make their influence felt by those whom he is later called upon to teach; that the council is fully alive to these considerations; and that the council will be on the high road to success if its subsequent deliberations are informed with as much knowledge backed with as high an enthusiasm as was shown at its inaugural meeting.

ESKIMO OF LABRADOR*

In the course of the Rawson-MacMillan Subarctic Expedition of the Field Museum (1927–28), Dr. W. Duncan Strong secured a large series of measurements and observations of living Labrador Eskimo and a small group of Montagnais-Naskapi Indians. When obvious mixed bloods and sub-adults are eliminated, the numbers were 137 Eskimo (58 males, 79 females) and 18 Indians (11 males, 7 females). Labrador Eskimo skeletons were also obtained, including thirty-two measurable skulls (17 males, 15 females), many with associated skeletal parts. Measurements made by Shapiro, Boas, Pittard, Duckworth and others have been added in this study. An unusual series is thus made available, comprising (1) an old stone grave series, pre-white, and earlier than 1770; (2) a mid-nineteenth century grave series (early Mission period); and (3) recent living (1880–1928).

The material is drawn from the Eskimo of the north-east coast of Labrador, a remnant of a population once extending to the Gulf of the St. Lawrence. While the influence of the Moravian Mission has been directed to the preservation of Eskimo culture and habits, adoption of Caucasian types of food appears to have introduced modifications of physique, especially in reduction of stature and in general bodily habit of fat.

In the investigation of the Eskimo of Labrador, the evidence of physical character must be invoked to aid in the elucidation of the archæological question. Briefly and in very general terms, the archæological problem is to determine the relation in the cultural sequence of pre-Thule, the Dorset and Thule cultures, and recent Eskimo. The evidence of physical anthropology is subject to very definite limitations, not least owing to the absence of skeletal material to be assigned to the Dorset culture.

It would appear that the culture of the Labrador Eskimo was most closely related to that distributed over the central Arctic, but retained more of the Thule culture than has survived in the central regions proper (T. Mathiassen). The Thule culture in the eastern Arctic is present only on pre-contact sites, except for a group on Southampton Island. Although Thule is considered to be the original Eskimo culture of the eastern Arctic, evidence has been presented suggesting that Thule may have been preceded by the Dorset people, though possibly in some places contemporaneous (D. Jenness).

In north-eastern Labrador evidence has been found of an earlier stone culture with Eskimo-like stone *ulus*, ground slate points and chipped scrapers. It contains almost nothing of the bone, antler, ivory and steatite artefacts characteristic of Thule, Dorset, and Labrador Eskimo (W. D. Strong); and this leads to the suggestion that the Eskimo cannot have been in Labrador for more than four hundred years.

By fitting ethnological detail into this succession of eastern Arctic cultures extending back into the prehistoric, several theories of Eskimo origin and migrations have been formulated, in which the crucial difference is the position to be assigned to the Caribou Eskimo of the interior, west of Hudson Bay. These people, in the view of K. Birkett-Smith, are a relatively unchanged remnant of the population from which all other Eskimo arose, while Matthiassen regards Thule as the original Eskimo culture and the first to spread eastward over the Arctic coast of America. D. Jenness, on the other hand, has recently put forward the suggestion of a triple division of the present-day Eskimo of Canada in which the natives of the Mackenzie River delta descend from old Thule people who migrated from Alaska to the eastern Arctic a thousand or more years ago, dropping colonies on the way; a second division on the Barren Grounds behind the Hudson, the inland Eskimo, survivors of the primitive Caribou; and descendants of the Eskimo who, about A.D. 1200, flowed out of the inland 'reservoir' and occupied the whole coast-line from Coronation Gulf to Labrador, overwhelming the earlier coast dwellers.

* Anthropometric Observations on the Eskimos and Indians of Labrador. By T. Dale Stewart. Material and Data collected by William Duncan Strong. (Anthropological Series, Vol. 31, No. 1) (Publication 462). Pp. 164+16 plates. (Chicago: Field Museum of Natural History, 1939.) 1·75 dollars.

On the grounds of cultural succession, it seems best to assume two reservoirs of population at the beginning of the Christian era, one in Alaska and one in the central Arctic, which must once have been united, presumably before the development of the earliest known culture in the west, the old Bering Sea culture.

Hence it follows that for interpretation of the Labrador physical type comparison with (*a*) the "Old Igloo" (Birnirk) type from Point Barrow, the oldest known, which has been identified by Hrdlička; (*b*) the Thule; and (*c*) the Dorset physical types is an essential. Unfortunately, as already mentioned, the Dorset type is unknown, while the Thule type was identified only recently (Fischer-Möller, 1937).

The indications of comparative study of the measurements as a whole are that the Labrador skull is small. Metrically, Greenland bears the closest resemblance to Labrador. The main physical changes indicated in a comparison of the old stone grave material and that of the recent grave series is that, as compared with the pagans, the Christians have smaller and shorter heads with longer and narrower faces, relatively higher orbits and relatively narrower alveolar arches. It is uncertain whether the nose has changed. Stature reconstructed from the measurement of the long bones is as follows: old stone graves, 161·4 (male), 150·3 (female); recent graves, 161·2 (male), 149·8 (female). This suggests that Eskimo stature has decreased in Labrador since the eighteenth century, a conclusion borne out by the findings on the living. Two stature groups can be distinguished: (1) a low-statured group averaging in the males about 160–162 cm., found chiefly in the east (Labrador, southern Greenland), and (2) a high-statured group, 164–166 cm., in the males, found chiefly in the west, but also among the Thule people in the east.

To sum up, it may be said that these data on the prehistoric Labrador Eskimo establish more firmly the fact that the physical type represented is much the same as that predominant in Greenland; it differs materially from that of the western longheads (Old Ingloo). Also it contrasts with that of the Thule. Assuming that Labrador was populated originally by Thule people, the type did not survive. Whether the Labrador and Greenland type was derived from a mixture of the Thule and Dorset peoples, or a representative of the latter alone, cannot be decided until the Dorset type is identified.

SEVENTY YEARS AGO

NATURE, vol. 1, April 28, 1870

Early Torpedoes

THE first of a series of articles on "The Science of Explosives as applied to Warlike Purposes" appears, and deals particularly with history of the use of explosives as floating or submarine mines and torpedoes.

The earliest form of marine mine appears to have been the 'explosion ship' used by the Dutch to destroy a boom or boat-bridge constructed across the Scheldt in 1585. Several flat-bottomed vessels loaded with gunpowder were sent against the boom, exploding when they reached it. A development of this was the 'floating petard' used by the English during operations in Rochelle in 1628; this consisted of a sheet-iron case filled with powder which was exploded by a match-lock mechanism set off by contact with an obstacle.

An American, Robert Fulton, seems to have been the first to use the term 'torpedo'. His device consisted of a metal vessel holding about 100 lb. of gunpowder and fitted with clockwork to release a flint-lock at a determined time. The machine was partly encased in cork so that it was a little heavier than water, and was attached by a line to a box float. The torpedoes were carried in harpoon boats, and connected by long lines with harpoons fired from small guns at the ship to be attacked. If the harpoon was successfully planted, the torpedo was drawn into the water by the line, the clockwork firing mechanism released, and the torpedo exploded by the time it had drifted near the vessel attacked. Demonstrations with these torpedoes were carried out before English naval authorities in 1805. A diagram of a torpedo and its harpoon is printed.

Extensive use was made of mines, or torpedoes as they were called, in the American Civil War, both mechanical and electrical means of ignition being used.

Legislation and Nature

"THE effect of Legislation upon Nature is one of those far-reaching subjects which men are only just beginning to investigate in a practical spirit. . . . Neither directly nor indirectly, in fact, can we touch Nature by our laws, without beginning a new chain of causes, the end of which we cannot foresee."

Mr. E. Goadby is discussing an item in the Budget introduced by Mr. Lowe. "The freedom of firearms from taxation affects their number in any district, the number of guns determines the number of small birds, and the number of our small birds affects the immunity of our fields from grasshoppers, cricket-moles, beetles, locusts, slugs, etc. Mr. Lowe was concerned for the security of life, for the prevention of early quasi-poaching habits, but his 1 *l.* tax may effect a revolution all the same."

Another topic also discussed by Mr. Goadby is the rating of woods and plantations. He refers to the incidence of insects in relation to trees, and concludes: "Disafforesting threatens to become as common in the nineteenth as enclosuring was in the sixteenth century. Are we wise to hasten it?"

THIS issue of NATURE completes the first volume of twenty-six weekly issues, price 4*d.* each. The volume includes 558 pages of text and 110 pages of advertisements.

FORTHCOMING EVENTS

[Meeting marked with an asterisk is open to the public.]

Monday, April 29

PHYSICAL SOCIETY, jointly with the CAMBRIDGE PHILOSOPHICAL SOCIETY (in the Cavendish Laboratory, Cambridge), at 3 p.m.—Discussion on "The Liquid State" (to be opened by Prof. J. E. Lennard-Jones, F.R.S.; other speakers: Prof. E. N. da C. Andrade, F.R.S., Prof. Allan Ferguson, J. Corner, Prof. J. D. Bernal, F.R.S., Prof. W. L. Bragg, F.R.S., Prof. R. H. Fowler, F.R.S., Prof. N. F. Mott, F.R.S.

Tuesday, April 30

ROYAL INSTITUTION, at 5.15 p.m.—Major-General Sir Robert McCarrison: "The Medical Aspects of the Use of Food".*

INSTITUTE OF PHYSICS (in the Lecture Hall, Kodak, Ltd., Harrow), at 7.30 p.m.—Prof. N. F. Mott, F.R.S.: "Oxidation of Metals and the Theory of Protective Films".

Thursday, May 2

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 4 p.m.—Prof. R. J. S. McDowall: "The Circulation in Relation to Shock".

Friday, May 3

PHYSICAL SOCIETY (in the Physics Department of the Imperial College of Science), at 5.15 p.m.—Discussion on "The Teaching of the Fundamentals of Electric and Magnetic Theory" (opening paper by Dr. G. B. Brown).

ROYAL INSTITUTION, at 9 p.m.—Prof. W. L. Bragg, F.R.S.: "The Symmetry of Patterns".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

TEMPORARY ASSISTANT LECTURER IN AGRICULTURE at the Essex Institute of Agriculture, Writtle—The Clerk to the Essex County Council, County Hall, Chelmsford (April 30).

TEMPORARY FULL-TIME LECTURER IN PHYSICS—The Principal, West Ham Municipal College, Romford Road, Stratford, E.15 (May 6).

DIRECTOR OF RESEARCH to the Institution of Automobile Engineers—The Chairman, Automobile Research Committee, 12 Hobart Place, S.W.1 (May 6).

SENIOR LECTURER IN CIVIL ENGINEERING at the University of the Witwatersrand, Johannesburg—The Secretary, Office of the High Commissioner for the Union of South Africa, South Africa House, Trafalgar Square, W.C.2 (May 15).

SCIENTIFIC ASSISTANT IN THE WATER EXAMINATION DEPARTMENT—The Clerk to the Metropolitan Water Board, New River Head, 173 Rosebery Avenue, E.C.1 (quoting 'Scientific Assistant') (May 24).

TEMPORARY ASSISTANT CIVIL ENGINEER—The Borough Engineer, Town Hall, Eastbourne.

ASSISTANT ENGINEER for the Drainage and Irrigation Department, Malaya—The Crown Agents for the Colonies, 4 Millbank, S.W.1 (quoting M/9114).

ENGINEER TRANSPORT OFFICER by the Government of the Gold Coast—The Crown Agents for the Colonies, 4 Millbank, S.W.1 (quoting M/9320).

A MINISTRY OF RECONSTRUCTION

THE measures advocated by Sir Gwilym Gibbon in a recent issue of *Public Administration* for the co-ordination of departments into groups with a minister for each, the Cabinet consisting of the Prime Minister and these ministers-in-chief and a few other ministers with few or no departmental duties, recall the report of the Machinery of Government Committee, of which Lord Haldane was chairman. Little or nothing has been done to implement the findings of that report since it appeared so long ago as 1918; but Sir Gwilym, in urging that it is imperative that this Cabinet directorate "shall be relieved of all but the matters of most importance, and that above all, it and its members shall have enough freedom from pressing duties to think of coming problems (as well as of current) well ahead of their coming", is indeed only restating the arguments and views of that report.

Lord Haldane's responsibility for the drafting of the Committee's report is well known, and its major recommendation, that every Department of State should be provided with its general staff and that a Ministry of Information and Research should be created for this purpose, was reflected in his presidential address to the Institute of Public Administration in 1922. Under the title "An Organized Civil Service", he appealed not merely for efficient and scientific administration and for the high tradition of self-sacrifice for public duty, but also for the forward-looking mind.

Lord Haldane did not conceal his doubts whether this outlook was being sufficiently encouraged in the Civil Service of Great Britain or in the universities from which its administrative officers are largely recruited, just as on another occasion he questioned the capacity of the older universities to train men of the requisite precise habit of mind. It is no reflection on the valuable work which in the last twenty years has been carried out by the Institute of Public Administration and elsewhere to suggest that we have no reason to be any more satisfied with the present state of affairs. In the organization of civil defence in the last few years, and also in the measures taken in the economic crisis of 1931, there has been all too little evidence of the forward-looking mind and appreciation of the importance of scientific management or a scientific outlook.

Better provision for inquiry, research and reflection before policy is defined and put into operation could undoubtedly have avoided some of the worst mistakes in evacuation and other operations. If, however, such mistakes can be overlooked, once they have been admitted and rectified, their repetition becomes intolerable, whether from the point of view of war effort or of the reconstruction to follow the War. It is this position which gives fresh pertinence to the report of the Machinery of Government Committee, the more particularly as some of the reconstruction proposals which were implemented after the War of 1914–18 were liquidated in the aftermath of the crisis of 1931.

In the first place, it will be noted that the Machinery of Government Committee was established under the Ministry of Reconstruction, and is itself an example of the organized thinking which was carried out in the last two years of the 1914–18 war period. A valuable feature of a recent broadsheet issued by P E P (Political and Economic Planning) on Reconstruction, 1916–1919, is the reminder it gives of the many reforms in law, in local government, in power supply and other fields, which we owe to men who during those harassing years and in such unfavourable circumstances proved themselves competent, not merely to organize victory, but also to think ahead boldly and with a precision justified by results when their proposals have been put to the test of practice.

The most cursory survey of the work of the Ministry of Reconstruction established in July 1917 and of the outcome of its activities will testify to the value of such work even in time of war, when victory is far from being in sight, and, indeed, of its essential importance if we are to realize the new world order which we look for after the present struggle. Unless the main underlying trends are analysed now and directed to constructive purpose in the light of possibilities and limitations which must persist whatever the outcome of the War, we may be once again in danger of losing the peace when we have won the war.

The Ministry of Reconstruction itself was liquidated in 1919, but in the Forestry Commission, the Electricity Commission, the Central Electricity Board, to mention only three public bodies, we are still able to benefit from the outcome of its deliberations. The grouping of the main-line railways, the reorganization of local government in 1930, and the Law of Property Act, 1925, were further results, and the work of the Whitley Committee on labour relations is another outstanding achievement, which has now provided a firm framework for industrial relations in Great Britain.

Besides its own particular activities, the Ministry of Reconstruction aimed at co-ordination as well as planning, and whether in dealing with the problems immediately following the cessation of hostilities—demobilization of man power, decontrol of raw materials and productive capacity, and generally setting the wheels of trade and commerce going again—or in those of the succeeding period of settled peace, it made contributions for which we owe a great debt to Lord Addison and his colleagues. During those years the country was equipped for the first time with a department devoted to research into questions of political science and to the encouragement of action on the lines ascertained.

The subsequent twenty years, however, afford no grounds for easy optimism concerning the extent to which the primary importance in reconstruction of organized thought, as distinct from executive action, is more widely recognized. Certain of the organizations brought into being by the Ministry of Reconstruction have already been discarded—for example, the Economic Advisory Council, which in 1930 was formed out of the Committee of Civil Research, itself a child of the Machinery of Government Committee. Moreover, in this very field, refusal to make full provision for co-ordinating economic policy is at least causing profound uneasiness in many minds. So, too, as a valuable article in the *Political Quarterly* by Dr. W. A. Robson shows, is the neglect to deal with such long-term problems as the location of industry, although the Barlow Commission has already reported.

These indications of *laissez-faire* mentality are profoundly disturbing. We cannot assume that refusal to face long-term problems involves the more vigorous and efficient handling of short-term problems. There is plenty of evidence of timid and unintelligent treatment of important short-term issues. Indeed, as Dr. Robson points out, the abandonment of the reports of the Royal Commission on the geographical distribution of the industrial population of Great Britain deals a fatal blow at the development of a scientific treatment of the problems of evacuation. Unless even greater mistakes are to be avoided, some attempt must be made at central control. Town and country planning have acquired a new and more important status. They should, as Dr. Robson urges, be placed in the hands of a strong central department, competent not only to deal with the special needs of the Service departments and the Government offices, but also to take over the task of directing the location of industry and formulating a national plan for the whole country.

The experience of the Ministry of Reconstruction affords evidence of what is possible and indeed essential even in the stress of war, and its achievements will well repay study at this time. All the experience of the last twenty years, however, reinforces the plea for planning ahead. The task cannot and should not be avoided in war-time. It is in no way an impediment to victory. On the contrary, so many of our war-time exigencies are entirely consistent with socially desirable peace-time purposes that the same planning ahead which best serves our immediate war-time purpose will contribute most to subsequent reconstruction. The many factors which in the last two decades have intensified the need for bringing to bear organized thinking and the acquisition of facts as a basis for action into the affairs of State, emphasize the need for adequate attention now to the problems of reconstruction

MR. FISHER'S VARIOUS ESSAYS

Pages from the Past
By H. A. L. Fisher. Pp. viii+238. (Oxford: Clarendon Press; London: Oxford University Press, 1939.) 10*s.* net.

THIS delightful book may easily become the most popular of Mr. Fisher's writings. It is wholesome medicine for the times in which we live because it takes our minds away from them. The longest essay is one dealing with the "Whig Historians", and, of course, for the most part defending them. Macaulay, Mackintosh and Sir George Trevelyan are the most prominent figures in it, and Macaulay never found a more stalwart—yet withal a discriminating—admirer. The cleverest paper is a sketch of what might have happened had Napoleon made his escape to North America and afterwards attempted the setting up of a new empire in the New World, which was at that time disturbed by many revolutions, centring round the figure—rather more heroic than Mr. Fisher presents him—of Simon Bolivar. There are charming pictures of the "Beauty of England", and a very curious account of a New College 'progress' when the Warden, accompanied by his junior outrider, used to drive round visiting all the neighbouring College farms, taking the homage of the respectful tenants and being solemnly entertained by the dependent folk of the holding. It is to be feared that this picturesque custom has now fallen into disuse, and we are the more obliged to Mr. Fisher for putting it on record. He says quite truly that the public—even the College public—are not aware of the extent of the agricultural interests of the colleges of Oxford and Cambridge. In our days the picturesqueness has been worn off by the motor-car, but science has come in to improve the agricultural methods by which the bursars guide the operations of the college tenants.

There is another essay in the volume which has a rather surprising title and will appeal especially to readers of this review. It is called "The Real Oxford Movement" and deals with the group of men who in the middle of the seventeenth century happened to come together in Oxford and formed the nucleus of what was afterwards removed to London and became the Royal Society. Mr. Fisher calls it the Real Oxford Movement, but he admits the existence of many others and would be the first to allow that other places, especially London and Cambridge, have a claim to preeminence in science. The latter will always stand first on the roll with the names of Newton and Darwin, and it was in the former that this "invisible college" first met which was transferred to Oxford during the years of 1648–1659.

The movement began with a small group of doctors and other earnest inquirers who sought the quiet of Oxford during the tumult of the Civil War, and it found in Oxford members of the University who had already begun "a free way of reasoning" of their own. It is these men whom Mr. Fisher describes so vividly and who were later to form the nucleus of the Royal Society, when it came into permanent public and authorized notice. They seem to have met mostly in Wadham, of which Wilkins, one of their members, was warden during 1648–59. He was primarily an astronomer, son of an Oxford goldsmith and with clever hands as well as mechanical tastes. He was a "most obliging and universally curious Dr.", who afterwards became bishop of Chester and the first secretary of the Royal Society.

But there were other men of greater originality who left more notable evidence of their scientific powers. William Petty was one of these. By turns cabin-boy, hawker and seaman he came back to England in 1646 after having become a physician by studies abroad. He ranks as an English classic by virtue of his "Essays on Political Arithmetic", which were the first attempt to apply to political problems the notions of number, quantity and measurement. He was an ancestor of Lord Lansdowne and would rank as the most brilliant of the group, had it not been for Christopher Wren, whose accomplishments entitle him to be considered the most versatile and famous of the group.

A great geometer and astronomer and anatomist, Wren added many buildings to medieval Oxford before he gave London its most conspicuous church after the Great Fire of 1665. He was at that time Savilian professor of astronomy at Oxford. When we add to these names that of John Evelyn who visited Oxford in 1654 when the group was in full activity, Robert Boyle who went to Oxford in 1654, and Robert Hooke who competed with Wren for the design of St. Paul's, one may wonder whether so brilliant a group of young men ever adorned English science at the same time before. They were all at Oxford about the same time at some period of their career and they well justify Mr. Fisher's title of the "Real Oxford Movement". It is a strange catastrophe in English history that so bright a growth should have died away into the apathy and ignorance which are described in the Oxford of Adam Smith and Gibbon in the next century.

There are several other essays, largely biographical, for example, Lord Balfour, John Morley, Philip Snowden and politicians in general, which make up a fascinating volume. Mr. Fisher was, of course, uniquely qualified to bring together recollections of Oxford, history and politicians, and it is done here with a special charm.

F. S. MARVIN.

PREHISTORY OF JERSEY

The Archæology of the Channel Islands
Vol. 2: The Bailiwick of Jersey. By Jacquetta Hawkes. Pp. xvii+320+12 plates. (Jersey: Société Jersiaise, 1939.) 25*s.* net.

THIS survey of the archæology of the Channel Islands was projected by Mr. T. D. Kendrick, by whom the first volume, dealing with the Bailiwick of Guernsey, was published in 1928. Other interests supervened, and in 1934 Mr. Kendrick passed his material relating to Jersey—field notes, and analyses of manuscript and published sources—to Mrs. Hawkes. This material she has re-interpreted and expanded in the light of the revolutionary ideas and discoveries which have supervened in European archæology since the first volume appeared, and now publishes as a review of the prehistory of the Bailiwick of Jersey.

The relics of the remoter past of the Channel Islands have long attracted the interest of antiquarians; while the island of Jersey earned no little notoriety of a less enviable kind in the annals of archæology by the mistaken, if grateful, act of generosity of the States of the Island when, in the early years of the nineteenth century, they made the embarrassing gift of one of their finest megalithic monuments to General Conway, the Lieutenant-Governor of the Island, by whom it was re-erected complete on his estate at Henley.

No little interest, of a more honorific character, has been aroused by these megalithic monuments, of which the Channel Islands present an astonishing assemblage, in view of the small size of the islands—Jersey, 44 square miles, and Guernsey, 24½ square miles only—while Guernsey can show two remarkable examples of the anthropomorphic sculptured menhirs characteristic of the cult of the Mediterranean goddess. This interest, however, was eclipsed by the discovery in 1910 of the teeth of Neanderthal man, associated with relics of a pleistocene fauna—mammoth, woolly rhinoceros, elk, horse and several deer—in the cave of La Cotte de St. Brelade then under excavation, but from the deposits of which Mousterian implements had been extracted so long before as the nineties of the preceding century.

Since the War of 1914–18, Jersey has not been passed by in the enhanced interest attaching to archæological investigation in the field; and the enthusiasm of the members of the Société Jersiaise, the local scientific society, has added much to knowledge of the facts of the island's prehistory, some of which is of wider than local bearing, as Mrs. Hawkes points out: notably Dr. A. Mourant's investigation of peat deposits and the quaternary geology of the island, the examination of the mound of La Hougue Bie, or Prince's Tower as it is known in local legend and popular parlance, which the Society purchased in the interests of scientific research, and the remarkable habitation site of Le Pinnacle, excavated by Father Christian Burdo and Major A. D. B. Godfroy in 1930–35, important for its contribution to stratigraphic evidence of a positive and negative bearing on the archæological story of the island, of which Mrs. Hawkes makes use with convincing effect.

The archæology of Jersey differs from that of the islands of Guernsey and Alderney in certain respects, of which some are of paramount importance to archæological interpretation, as Mrs. Hawkes demonstrates. In the first place, Jersey is the only one of these islands in which palæolithic man appears. Nor is Neanderthal man of the caves, with his Mousterian implements of the Middle Palæolithic, the earliest of his compatriots to which the Jerseyman can point. Four palæolithic flint implements, unfortunately of unknown origin, have been found on the beaches of the island, of which two are undoubtedly Acheulean. Why palæolithic man with his associated fauna should appear in Jersey and not in Guernsey, distant only 18 miles away, is explicable only on the inference from the evidence of a fauna which could not be maintained on a small island and the depth of intervening channels, that whereas in part of the quaternary period Jersey must have been affected by a land elevation which joined it to the adjacent mainland of France, Guernsey was not so joined. The absence of Upper Palæolithic man from Jersey, and the failure of intensive search to produce any certain evidence of mesolithic man even on the habitation site of Le Pinnacle, argues a subsidence in which Jersey once more became an island; but a further elevation and consequent union with France again is argued as possible for the megalithic period. This would account for certain differences observed in the culture of the island, upon which Mrs. Hawkes enlarges.

Whether Jersey was already occupied on the arrival of the megalithic culture, which is the most conspicuous element in the cultures of the Channel Islands, is a question which Mrs. Hawkes argues with much acumen on the complex evidence by excavation on occupation sites and mounds. For here, with the megalith and its associate the bell beaker, which, as Mr. Kendrick has pointed out for Guernsey, belong to the Morbihan and are derivate ultimately or in certain instances possibly more immediately from the Iberic peninsula, are also associated elements of the Chassey culture, the vase support being conspicuous in Jersey by the frequency of its occurrence, and another strain of the megalith, the long cist with holed stone, which is characteristic of the Seine-Oise-Marne culture. Arguing from an analysis of the culture of the adjacent Normandy-Breton mainland, Mrs. Hawkes sees in the characteristic culture of Jersey a culture peripheral to this region—assuming that Jersey was then joined to the mainland in which Chassey, SOM and the megalithic culture of the Atlantic coalesce, while the megalithic culture of Guernsey, in which the two former are absent, becomes a touchstone of a western origin for the elements of any given cultural complex.

That the megalithic culture of the Channel Islands persisted in degenerate form for a prolonged period and long after it died out elsewhere is more than probable. After this rich, not to say extravagant, efflorescence—a manifestation of local prosperity—dies down, neither island has anything to show down to Roman times that is at all comparable, with the exception of the remarkable gold torque found in Jersey, a find which is as puzzling to the archæologist as it is unexpected. The torque is in itself almost unique, for its length of 4 ft. 7½ in. makes it almost the largest known, being second in length only to the Tara torque, which is 25 cm. longer. Its weight is 476 grams. It belongs to a class which in Britain is assigned to the Middle Bronze Age; but its presence in Jersey, Mrs. Hawkes holds, is explicable only if its introduction into the island took place not in a period when the island was culturally poor, but rather in the later Late Bronze Age, when intercourse with Britain was intensified.

The remaining detail of the record must be passed over. Enough has been said to indicate the power of cultural analysis which Mrs. Hawkes has successfully, if as she admits not finally, brought to bear upon a cultural complex which is something in the nature of a jigsaw puzzle. She pays a just tribute to the work of the members of the Société Jersiaise, which in its turn has published her work with a lavish but deserved generosity, while in the honorary secretaries of the Society, Major Lacy Rybot and Mr. Emile Guiton, she has had as collaborators an artist and a photographer worthy of her text.

TRAVELS IN PERU

A Forgotten River
A Book of Peruvian Travel and Botanical Notes. By Christopher Sandeman. Pp. xii+300+15 plates. (London: Oxford University Press, 1939.) 12*s.* 6*d.* net.

A "THREE-MONTHS Odyssey" is told in diary form, a thousand miles circular tour through northern Peru, starting from Lima, following old trails better known in the seventeenth century than to-day. The Andean divide crossed at 16,000 ft., the Huallaga River was reached where it becomes navigable by rafts and canoes at 2,640 ft. above the sea. Four hundred miles here were practically forgotten; the last navigators were Smyth and Lowe in 1834, and Herndon in 1850. A raft was built of the light balsa (Ochroma) wood simply by lashing long poles together by lianes, the whole rather irregular and loose so as to give to the frequent collisions with banks and fallen trees as well as the strandings in shallow water. The three weeks voyage was exciting enough, rapids, whirlpools, canyons and waterfalls using up three rafts in succession, but it did not give much scope to the botanical proclivities of the passengers. The river showed remarkably little change in the hundred years that had elapsed. Its course was through tropical forest, part of the once Jesuit empire that continued throughout the seventeenth century to the expulsion of the order in 1768. It is useful to observe that this conquest was based on the natives' natural love for music, used in the first place as a lure and later as the governing feature of each community.

At Yurimaguas, 580 ft., the old east-to-west trail was reached and this was followed westward across the Andean Cordillera. It started as a mule trail through the tropical rain forest, innumerable streams and no bridges. Then from Moyobamba at 2821 ft. it became much worse as it crossed the first ridge at 12,000 ft., often in deep gullies created by the feet of traders from Inca and earlier civilizations, the higher parts of the ridge scored by the winds so that only stunted bushes and grass could grow. A descent to Chachapoyas, 7638 ft., strengthened the travellers to cross the Calla Calla Pass, then the descent to the Maranon River, whence the Amazon falls 3000 ft. to the sea in about as many miles. Again a further pass and finally the last part of the journey by motor along the completely bare and barren coastal plain.

There is little of scientific interest in this book of a plant-collector; but its simplicity, complete honesty and pleasant sense of humour cause it never to weary. The reader will form a better idea of this almost forgotten country from it than from a more pretentious work. The task of opening it up, with its numerous parasitic diseases and its unwanted products, is enough to depress any Government.

APPLIED AERODYNAMICS

Applied Aerodynamics
By Prof. L. Bairstow. Second edition. Pp. xviii+808+27 plates. (London, New York and Toronto: Longmans, Green and Co., 1939.) 63*s*. net.

THE first edition of this book was reviewed in NATURE of March 25, 1920. In general the appearance of a second edition of a standard text-book calls for little comment, but in the present case the changes are so far-reaching that the book is practically a new work. The period immediately before and during the War of 1914-18 was one of intensive pioneer research both on the theoretical and experimental side, and in this research Bairstow took a leading part. The first edition, based on the work done during that period, omits all reference to boundary layer theory, the Kutta and Joukowski theory of two-dimensional aerofoils, the circulation theory of lift, and the Lanchester-Prandtl theory of finite aerofoils. All this is remedied in the present edition, and for that reason alone it can be seen that the author's statement that about three quarters of the book is new material is easily justified.

The author has adhered to the general plan of the first edition, namely, to provide principles to interpret the results of experience, and to give adequate experimental results to illustrate the subject-matter.

The book opens with a short but interesting chapter on the history of the development of applied aerodynamics. Then follow chapters on the principles of flight, aerodynamic measurements, laboratory tests, aerial manœuvres, similarity and scale effect. The next five chapters start from first principles to build up the theory of aerofoils at moderate speeds when compressibility of the air is unimportant, and at high speeds when the properties of aerofoils are materially different from those at low speeds. These chapters contain detailed development of a large amount of ordinary hydrodynamical theory, potential, viscous, and two-dimensional boundary layer flow, including the detailed application to an actual aerofoil. There is also a short chapter introducing the statistical theory of turbulence.

The three remaining chapters deal with air-screws, performance, and stability. In connexion with stability the author explains that during the past twenty years economic pressure has led to intensive activity directed to increase of speed and load, and as a consequence a very large amount of information is available from which to choose illustrative examples of steady flying. The experimental investigation of more complex motions has been less thoroughly pursued and in particular there has been less systematic study. It has therefore not been possible to use modern examples to illustrate adequately the principles of stability, and for these sections the examples of the first edition have been retained. Nevertheless, an account of Glauert's non-dimensional system of equations would have been welcome here, as developed, for example, in the excellent study of stability given by B. Melvill Jones in volume 5 of Durand's "Aerodynamic Theory".

In the preface the author states that this book is in no sense an attempt to produce a text-book of designs, but aims at the extraction from the great mass of data of those elements which necessarily form the basis of all design. That this aim has been attained in full measure cannot be doubted. The book is full of apt numerical tables, graphs, and diagrams. There are also twenty-seven excellent plates, including one of the kite balloons now so prominent in the sky of London and elsewhere. Incidentally, an interesting conclusion from the investigation of the aerodynamic force on these balloons, is that the balloon is blown to a definite position by light winds, and will then maintain this position as the wind velocity increases.

The reviewer may perhaps be permitted two grumbles: (i) the apparent absence of definitions of common terms such as *aspect ratio* and *camber*, (ii) the very high price of this excellent volume.

L. M. MILNE-THOMSON.

THE THEORY OF NUCLEAR FORCES*

By PROF. R. PEIERLS,

UNIVERSITY OF BIRMINGHAM

THE forces between the constituents of a nucleus are 'short-range' forces, which have no appreciable effect over distances of more than a few times 10^{-13} cm. Hence it is impossible to find the laws of force by extrapolation from large-scale observations (as in the case of Coulomb's law) and the only possible lines of attack are either, to deduce the law of force from direct observations on the properties of nuclei, or to derive them from some simpler, and more general, laws.

Using the direct experimental approach, it is best to start from phenomena which involve only two particles, since only these permit an unambiguous theoretical interpretation. This group consists of the properties of the deuteron, including its disintegration, and the scattering of protons and neutrons by hydrogen.

Practically all experiments are carried out in conditions in which the de Broglie wave-length of the particles is greater than the range of the forces, and this has the effect that one need consider only those states of motion in which the motion of one particle with respect to the other has no angular momentum. (In all other states of motion the centrifugal force prevents the particles from approaching sufficiently close for any interaction to take place.) Moreover, so long as the wave-length is greater than the range of the force, the effect of the field of force is largely independent of the exact variation of force with distance within the range, and depends approximately only on one constant, which may be called the 'strength' of the field of force. (In the case of a potential of the type of a potential well, this strength is approximately proportional to the depth times the square of the width.)[1]

In the experiments on proton–neutron interaction two possible cases are discussed, according to whether the spins of the two colliding particles are parallel or opposite (in the case of like particles, Pauli's principle ensures that, so long as there is no orbital angular momentum, the spins are necessarily opposite) and the strength of the interaction may be different for these two cases. For the case of a proton and a neutron with parallel spin, the strength constant can be obtained from the binding energy of the deuteron; for those with opposite spin, it follows from the scattering of neutrons by protons, since in this scattering the effect of the neutrons with parallel spin can be allowed for once their strength constant is known. The very high cross-section for slow neutrons is an indication that the strength constant of the interaction for neutrons with opposite spin is either just sufficient or just insufficient to give rise to a bound state of the deuteron with no resultant spin[2]. The choice between these alternatives can be made by means of the scattering of neutrons in *para-* and *ortho*-hydrogen where, because of interference, the results depend on the phase of the wave scattered by each proton. The result is that the force is just insufficient to give a bound state[3].

For the proton–proton force, the strength can be derived from measurements of the scattering of protons in hydrogen.

Once these strength constants are known it is possible to calculate all other observable quantities, namely, the energy variation of the proton–proton and neutron–proton scattering, the photo-effect of the deuteron, etc., to the degree of approximation in which the ratio between the range of the forces and the de Broglie wave-length is negligible. The fact that these calculations give approximate agreement with observations serves as a check on the initial hypothesis of short-range forces.

Actually, all results of this simple theory have to be supplemented by correction terms involving the range. If the experimental data were accurate enough, it should thus be possible to estimate the range of the forces. The use of these correction terms requires greater accuracy than is at present available in the data on neutron–proton scattering, and the determination can only be carried out in the case of the proton–proton scattering, in which more accurate data have been obtained. The result of this is that the 'range' for this interaction is about $1\cdot2 \times 10^{-13}$ cm. The experimental data are even accurate enough to yield a certain amount of information on the actual dependence of the force on distance[4].

More information on these points would be obtained by measuring the neutron–proton scattering at medium energies with higher accuracy, or by observations at higher energies including, in particular, the angular distribution of the scattered particles.

An important contribution to the problem was the discovery by Rabi and others of a quadripole moment of the deuteron[5]. This proves that the neutron and proton have a tendency to have their spins in the direction of the line joining them, rather than at right angles to it. This implies obviously that the forces are not central, but that the potential energy depends on the angle between the spin direction and the line joining the two particles. Although all the calculations referred to above were carried out on the assumptions of central forces, the results remain practically unchanged. For opposite spins, which is the only case of interest for proton – proton interaction at low energies, the force must still be central, since the resultant spin is zero and hence does not set up a preferential direction; for parallel spin, the fact that the force is not central means that the angular momentum due to the motion of the particles is no longer constant but fluctuates. Hence the motion in the state of lowest energy is no longer one with zero orbital angular momentum; it can be shown that the state of motion is a mixture of a state with zero angular momentum and one with two units (*S* and *D* states in spectroscopic notation). From the electrical quadripole moment one can estimate that the contribution of the *D* state amounts to only a few per cent[6].

---

*Based on lectures given at the Royal Institution on January 17, 24 and 31.

However, an appreciable non-central force is required to produce even this small effect, since in the *D* state a very strong centrifugal force has to be overcome. It seems probable, therefore, that the non-central forces must represent an appreciable fraction of the total force. Yet, again owing to the effect of the centrifugal force, no appreciable influence of this *D* state should be expected on the other observable phenomena, except possibly on some finer features which have not yet been thoroughly investigated. Thus the approximate agreement with the experimental evidence, and the estimate of the range remain practically unaffected by the correction terms.

The data on the strength and the estimate of the range give the same answer, within the experimental error, for the proton – proton and proton – neutron interactions for opposite spins, and the suggestion has therefore been made that these two forces are exactly the same, except for the electrostatic interaction between the protons ('charge-independence hypothesis')[7].

From the fact that the charge of stable light nuclei is about half their mass, and that only a small change is produced in the energy of a light nucleus if in its constituents the number of neutrons and the number of protons are interchanged, has further led to the belief that the nuclear forces are symmetric in proton and neutron, that is, the neutron – neutron interaction is exactly the same as the proton – proton interaction, except for the effect of the electric forces[1].

Turning now to the evidence from nuclei containing more than two particles, this is usually discussed on the basis of the assumption that the forces are additive; that is, that the interaction force between two particles is not affected by the simultaneous presence of a third particle. Beyond its simplicity and the fact that it holds in the atom, this assumption is not founded on any evidence, and, in fact, there are certain theoretical arguments against it[8]. However, without this assumption the available evidence is insufficient to draw any conclusions at all, and one must therefore use the assumption of additivity as a working hypothesis, which may at a later stage be disproved. Moreover, most of the theoretical work on the nuclei of weight 3 and 4 was done before the discovery of the quadripole moment of the deuteron, and hence central forces were used. It is likely that the directional dependence of the force will not be negligible in these problems, but its precise effect has yet to be investigated.

So far as the calculations go, they show that the mass defects of the nuclei of mass 3 and 4 are very sensitive to the range of the force, and that the range required to give the right values is roughly of the same order of magnitude as that obtained from scattering experiments[1,9]. Quantitative agreement, however, was not obtained. The laws of force used in these calculations were usually restricted by adopting the charge-independence hypothesis, and also by assuming that the range of the force was the same for parallel and for opposite spins. Whether the remaining discrepancy is due to these restrictions, or to the assumption of central forces, or whether it represents a failure of the additivity, remains to be seen.

For nuclei beyond ^{4}He, the observed binding energy ceases to rise rapidly with the number of particles. This fact, often briefly referred to as 'saturation', obviously means that the constituent particles of a large nucleus do not *all* attract each other with the same forces with which the constituents of a helium nucleus attract each other. This may be due to several reasons. For one thing, the additivity of the force might fail, and the attractive force between two particles may depend on the number of other particles in the immediate neighbourhood. This dependence might be such as to ensure that the total potential energy per particle always remained below a certain saturation value. A possible description on these lines has been put forward by Teller, Critchfield and Wigner[10], but the idea has not yet been pursued very far.
